To capture user's QoE, the streaming methods should be known at first since various applications have different requirements on QoE (Juluri et al. 2013). The metrics to measure the QoE have two types: objective metrics and subjective metrics. The metrics can be measured on either network side or client side by different measurement tools.

Streaming method is one of the most important factors affecting QoE. The widely used streaming technologies include real-time streaming (RTS) (Mazhar et al. 2018), HTTP progressive downloading (HPD), and HTTP adaptive streaming (HAS) (Liu et al. 2013; Zhang et al. 2012). All of them are able to enable users to start the playback once the part of the video is downloaded. However, due to their different transmission technologies, their quality impairments are not same. For example, RTS is mainly used in low-latency interactive applications, such as live streaming and video chatting. It is not only sensitive to video quality, but also to round-trip delay.

QoE metrics are used to assess the quality of video streaming. It can be classified into two categories: (Eswara et al. 2018) metrics and (Ghadiyaram et al. 2019). Objective metrics are the metrics which can be quantified with a measurement tool, such as bit (Xu et al. 2019) and delay. These metrics are objective and easy to be measured. However, they have only indirect impacts on users' experience with the service. Subjective metrics are the direct QoE feedbacks from users. Users rate the video service on a controlled environment. However, subjective metrics are susceptible to bias because users' QoE could be varied from one subject to another.

The techniques to measure QoE are also important for video streaming. Video streaming is an end-to-end service. There are multiple

parties participating in it, such as content providers, content-distribution-network (CDN) providers (Mangla 2019), and (Krishnamoorthi 2017). They view the end-to-end streaming from different perspectives, thus the QoE can be measured with the different measurement methodologies and tools.

Definitions

Wireless indoor localization systems locate the target's position in indoor environment, where the GPS signal is obstructed by walls of buildings. Current wireless indoor localization systems can be implemented with different techniques like Wi-Fi, Bluetooth Low Energy (BLE), radio frequency identification (RFID), ultra-wideband (UWB), and so on. The quality of service (QoS) in each indoor localization system is measured with accuracy, time delay, computational complexity, and availability.

Historical Background

How to obtain the position of the target precisely is always an important problem to solve, which plays a special role no matter in military or people's daily life. The most famous and applicable positioning system is Global Positioning System (GPS) built with huge amount of resources by the United States in the 1970s. The GPS system provides critical positioning capabilities to military, civil, and commercial users around the world with relatively high QoS. However, because the radio signal is obstructed by solid object like walls, GPS is not functional in indoor environment. Thus, the research of indoor localization is an urgent need which possesses a huge potential.

In the early stage of the 1980s, technologies like infrared or ultrasonic wave is adopted, such as the Active Badge and Active Bat system which are developed by Cambridge University. These systems can achieve high accuracy in indoor environment but have many limitations like coverage area and cost. In recent years, wireless radio frequency (RF) indoor localization, which can utilize radio frequency such as Wi-Fi and Bluetooth, attracts people's attention. The low-cost and easy-deployment properties of RF indoor localization system are beneficial to the large-scale deployment and also enhance the QoS in indoor localization.

In 2000, Microsoft published RADAR System (Bahl and Padmanabhan 2000), which is the world's first Wi-Fi signal strength-based indoor localization system but limited in accuracy and availability. Based on RADAR System, many researches have been done, and the QoS in indoor localization is enhanced gradually. Specifically, Youssef proposes the Horus system (Youssef and Agrawala 2005), which identifies different causes for the wireless channel variations and addresses them to achieve high accuracy. The EZ localization algorithm (Chintalapudi et al. 2010) models the constraints of environments by analyzing wireless propagation, to save pre-deployment efforts. Zee system (Rai et al. 2012) makes the calibration zero-effort, by enabling training data to be crowdsourced without any explicit effort on the part of users. Wen presents a general prob-

abilistic model (Wen et al. 2015) to explore the fundamental limits of Received Signal Strength (RSS) fingerprinting-based indoor localization. Mei (Wang et al. 2016b) evaluates how the temporal correlation of the RSS can influence the reliability of location estimation. Last but not the least, (Wang and Katabi 2013) introduces a fine-grained RFID positioning system that is robust to multipath and non-line-of-sight scenarios.

The researches above are all based on the Received Signal Strength Indicator (RSSI). However, RSSI suffers from dramatic performance degradation in complex situations due to multipath fading and temporal dynamics. Thus, nowadays channel state information (CSI) has attracted many researchers' attentions, and some pioneer works have demonstrated submeter- or even centimeter-level accuracy. For example, Phaser system (Gjengset et al. 2014), with the adoption of CSI, enables phased array signal processing for commodity Wi-Fi APs. SpotFi (Kotaru et al. 2015) accurately computes the angle of arrival (AOA) of multipath components by the measurable changes in CSI. LiFS (Wang et al. 2016a) uses CSI to realize device-free localization, and Chronos (Vasisht et al. 2016) enables a single Wi-Fi access point to locate clients with CSI.

Foundations

A typical wireless RF indoor localization system is consisted of three parts: measurement technique, selected feature, and mapping method. A basic localization procedure of wireless indoor localization is like the following: First, the device with the specific measurement technique will measure some monitoring information from the indoor environment. Then, the device extracts some features from the monitoring information. Finally, with the mapping method, we can map these features into real positions.

Specifically, the first part is measurement technique. There are four common types of measurement technique: Wi-Fi, RFID, BLE, and UWB. Here are the details of the four techniques:

- *Wi-Fi*: Wi-Fi is a technology that allows devices to be connected into a wireless local area network (WLAN). It is very popular and widely used in homes, hotels, airports, and shopping malls, which makes Wi-Fi one of the most eye-catching wireless technique in the field of indoor localization. With a high availability, the QoS of Wi-Fi-based system is also largely improved. Typically, a Wi-Fi system consists of some fixed access points (APs), which are largely deployed in easy-to-access location, and the network administrator knows the distribution of the APs. Therefore, Wi-Fi-based localization systems can easily reuse the existing WLAN infrastructures in public or private indoor environments, which lower the cost of deployment for localization.
- *BLE*: Bluetooth is a wireless technology standard that enables short-distance data exchange between devices. Many types of devices like mobile phones, laptops, and tablets are implanted with Bluetooth, and many connected devices can form a Bluetooth cluster. In Bluetooth-based localization systems, the position of devices can be located by the effort of other mobile devices in the same Bluetooth cluster. BLE is a new technique based on Classic Bluetooth, aiming at providing considerably low power consumption and cost while maintaining a similar communication range. With the availability increasing, the QoS of BLE is also enhanced.
- *RFID*: RFID is a communication technology that can identify specific targets through radio signal and then reads, writes, or stores data into a RF-compatible integrated circuit. RFID-based localization systems are commonly deployed in complex indoor environments, like offices and hospitals. There are two kinds of RFID: passive RFID and active RFID. The tags with passive RFID are usually small and inexpensive, but short in accuracy, which leads to lower QoS. On the contrary, with higher-cost and energy-consuming properties, active RFID could achieve better accuracy and shorter time delay, leading to high QoS.

- **UWB:** UWB is a carrier-free communication technology that can transmit data with nanosecond or picosecond non-sinusoidal pulses. By sending extremely low power signals over a wide spectrum, the UWB can achieve high data transmission rate from 100 Mbit/s to 100 Gbit/s in a range of 10 m. For UWB pulses having a duration less than 1 ns, it is possible for UWB signal to pass through the walls and reduce the multipath distortion. With submeter or even centimeter accuracy, UWB-based localization system can achieve high QoS. However, the cost of UWB device is expensive, which is short in applicability.

The second part is a selected feature. There are generally three kinds of it: power features, time features, and angle features. Such features can be extracted from the monitoring information, which is collected by the measurement technique. Specifically, RSSI and CSI are the most common monitoring information categories.

RSSI is a kind of signal strength information collected from the MAC layer of the mobile device. It can characterize the attenuation of radio signals after propagation. RSSI is a typical power feature and accessible with most wireless technique. For RSSI is easy to monitor and handily access, it has been widely adopted in both geometric mapping and fingerprinting localization systems. RSSI-based indoor localization can achieve meter-level high accuracy in some simple environments. However, the QoS of RSSI-based indoor localization in complex indoor environment is unsatisfactory, due to multipath fading and temporal dynamics. Generally speaking, traditional power features like RSSI could only remain room-level accuracy in complex environments.

CSI is a kind of channel response information collected from the PHY layer of the mobile device, which can show the channel response in 802.11 a/g/n. For CSI is collected from lower layer than RSSI, there are more fine-grained information and features contained in CSI. Various power, time, and angle features could

be extracted from CSI. Particularly, CSI is able to characterize multipath problem. Compared to RSSI, CSI holds more potential for better QoS in real complex indoor environments.

Specifically, from the channel response, the amplitude of signals in time domain or frequency domain could be extracted as the power features. Typical time features extracted from CSI include time of arrival (TOA) and time difference of arrival (TDOA). For example, Chronos (Vasisht et al. 2016) utilizes different channels of single Wi-Fi to extract TOA, which achieves high QoS of decimeter accuracy. Angle features like angle of arrival (AOA) provide a different thought for geometric mapping, which is utilized in SpotFi (Kotaru et al. 2015) with the help of subcarriers' information.

The usability of channel response is much lower than RSSI, for CSI is rather new and previously it could only be measured by professional equipment. However, with the development of Wi-Fi and orthogonal frequency-division multiplexing (OFDM), the situation has been greatly improved. Nowadays in 802.11 a/g/n environment, channel response could be easily extracted from off-the-shelf OFDM receivers. In recent years, numerous efforts have been paid on CSI to improve the QoS of wireless indoor localization.

The last part is mapping method, which is adopted to convert physical measurements into real positions. Specifically, geometric mapping and fingerprinting are the most common mapping methods.

In geometric mapping, distance and direction to the reference points could be the intermediate geometric parameters. These parameters could be derived from the physical measurement. Then, with certain geometric algorithm like triangulation, such parameters could be converted into real positions. Specifically, according to the geometric properties of triangles, there are four common methods of triangulation: RSS, TOA, TDOA, and AOA. RSS is easy to get, however, with the property of fluctuation in indoor environment, leading to the decrease in QoS. TOA can accurately derive the distance. But common devices are not capable to get the precise TOA. TDOA

utilizes the difference of arrival time between receivers, which is easier to implement compared with TOA. AOA determines target's position with the help of angles between transceivers.

Different with geometric mapping, fingerprinting is a pattern matching method. There are two phases in fingerprinting: offline training phase and online position determination phase. In the offline training phase, the basic idea is to pre-collect the selected features of all the possible locations in the area and build a fingerprint database to store the collected data related to the locations. Then in the online position determination phase, the location-related data of the position to be located is measured and sent to the fingerprint database. The database will return the location corresponding to the best-fitted fingerprint data. Generally speaking, fingerprinting method costs more effort, for it needs to build and frequently update the fingerprint database.

Compared to geometric mapping, fingerprinting method lowers the requirement of physical measurement. However, to avoid confusion and ensure the QoS of fingerprinting database, the fingerprint data of the same location collected at different time stamps should be close to each other.

Here is a typical example of wireless indoor localization. SpotFi (Kotaru et al. 2015) is a CSI-based Wi-Fi indoor localization system. There are three steps of SpotFi: First, use CSI to estimate the AOA and time of flight (TOF) of different multipath components of a target's signal arriving at the AP. Then, estimate the likelihood that each AOA and TOF pair is the one corresponding to the direct path between the AP and the target without any reflections. Finally, use above information to calculate the most likely location of the target that could have produced the observed RSSI and estimated AOA. The experiments in a multipath-rich indoor environment show that SpotFi has a remarkable QoS, which achieves a median accuracy of 40 cm and is robust to indoor hindrances such as obstacles and multipath.

Different from the typical wireless indoor localization system, there is a new trend of wireless indoor localization called passive

detection (device-free localization). Passive detection means that the system can detect the presence of or even locate a target by the deployed wireless monitors, while there is no any detectable device on the target. The principle of passive detection is that when a target object presents and moves in the area of interest, there must be some certain changes of the received signal features on the wireless monitor side. By analyzing the changes and adopting the proper algorithm, the device-free target could be located.

Key Applications

Wireless indoor positioning systems have been designed to provide location information of persons or devices in indoor environment. It enables devices to determine the target's position and makes the position of the target available for position-based services such as navigating, tracking, or monitoring in indoor environment.

Providing QoS support at the distributed wireless MAC protocol; QoS-capable MAC; QoS provisioning at the MAC layer

Definitions

In distributed wireless networks, a QoS-aware medium access control (MAC) protocol is used not only to address the contention and collision problem among mobile or fixed users sharing the same physical medium and the improvement of channel utilization but also to provide some QoS guarantees for users in, for example, terms of minimum throughput, maximum frame delay,

maximum variation of frame delay (jitter), and maximum frame loss ratio.

Historical Background

In general, the QoS-aware distributed MAC protocols evolve from the MAC protocols only supporting best-effort services. The first MAC, ALOHA (or pure ALOHA) (Abramson 1970), started out in Hawaii in the early 1970s, is a random access protocol proposed for packet radio networks. ALOHA and its improved version slotted ALOHA (Roberts 1975), as well as many early MAC protocols built based on Carrier Sense Multiple Access (CSMA) mechanism such as Multiple Access with Collision Avoidance (MACA) (Karn 1990) and Floor Acquisition Multiple Access (FAMA) (Fullmer and Garcia-Luna-Aceves 1997), aim at increasing network throughput by reducing collisions and/or solving hidden terminal and exposed terminal problems (Cheng et al. 2006).

However, as heterogeneous traffic emerge, QoS support with service differentiation at the MAC layer becomes indispensable. For example, delay-sensitive traffic such as voice may need a higher priority than the traffic such as data. To this end, both types of MAC protocols, enabling statistical priority and strict priority, were proposed. The Enhanced Distributed Channel Access (EDCA) function of IEEE 802.11e (IEEE Std 2007) and the Black-Burst (BB) contention scheme (Sobrinho and Krishnakumar 1999) are two well-known examples, belonging to each of the aforesaid types.

To achieve fine-grain QoS guarantee beyond priority-based MAC protocols, newly developed MAC protocols (e.g., distributed PRMA (Jiang et al. 2002)) also integrate with the function of resource reservation. With frame or slot reservation, it is possible to guarantee strict delay bound for voice packet, which is difficult if contention is unavoidable for every voice packet.

It is noteworthy that different wireless networks can have quite diverse QoS requirements. Furthermore, the QoS requirements and the tailored MAC protocols of a wireless network

also evolve with its applications and hardware advancements. A typical example is wireless sensor network (WSN). In the early stage, efficient data delivery (so throughput) was not its first priority, and more considerations had been given to how to extend the lifetime of the network effectively (Huang et al. 2013). However, the availability of low-cost hardware and rapid development of tiny cameras and microphones have enabled a new class of WSNs: multimedia or visual wireless sensor networks, which bring forward new QoS requirements of MAC on delay-bounded and reliable data delivery (Yigitel et al. 2011).

Foundations

In general, QoS provisioning at the MAC layer could be designed by following two principal approaches: prioritized, based on differentiated services (DiffServ) architecture, and parameterized, based on integrated service (IntServ) architecture (Natkaniec et al. 2013). DiffServ is a coarse-grained, class-based mechanism for traffic management. It operates on the principle of traffic classification, where each frame is managed and served at nodes along a delivery path according to its traffic class, rather than differentiating network traffic based on the requirements of an individual flow. In contrast, IntServ is a fine-grained, flow-based mechanism, in which to satisfy a flow's strict QoS requirements, deterministic capacity has to be reserved along the delivery path in advance. However, in a distributed wireless network, as the transmission is usually quality-unreliable and prone to collisions (thus somewhat capacity-unpredictable), DiffServ-based QoS provisioning is found more reasonable for a QoS-aware distributed MAC protocol.

In the existing distributed MAC protocols, the following mechanisms are employed frequently to provide QoS in distributed wireless networks, namely, backoff differentiation, InterFrame space differentiation, jamming, frame aggregation, frame manipulation, reservation, and alternating

contention period (CP)/contention-free period (CFP) (Natkaniec et al. 2013).

Backoff differentiation supports traffic differentiation by extending the basic function of backoff, assigning different contention window parameters for different traffic classes. For example, as compared with the basic Distributed Coordination Function in IEEE 802.11a or b, the EDCA function of IEEE 802.11e defines four access categories (ACs): Voice (Vo), Video (Vi), Best Effort (BE), and Background (BK) (IEEE Std 2007). Each AC has its own contention window minimum and maximum values ($CW_{\min}[AC]$ and $CW_{\max}[AC]$). To give preference to high-priority traffic, the contention window of high-priority traffic should be smaller than that of low-priority traffic.

InterFrame space differentiation is usually used together with backoff differentiation. Taking the EDCA function of IEEE 802.11e as an example, instead of using Distributed InterFrame Space (DIFS) for all traffic class, the backoff counter of traffic class AC may begin decrementing after the Arbitrary InterFrame Space (AIFS) associated with its own AC, AIFS[AC] (IEEE Std 2007). So, differentiated access control is provided by letting high-priority traffic have shorter AIFSs. However, neither backoff differentiation nor InterFrame space differentiation can provide strict priority differentiation. It is possible that a node with high-priority traffic fails in channel access when contending with a node with low-priority traffic.

To maintain better traffic differentiation, jamming, sometimes named black bursts (Sobrinho and Krishnakumar 1999) or busy tones (Haas and Deng 2002), can be utilized. The basic idea of jamming is to let a contender send a jamming signal of which length is proportional to the priority; thus other contenders will quit channel access contention if detecting a longer jamming signal. To ensure a good priority differentiation resolution, the setting of the jamming signal length should take into account the network area or the largest propagation delay in the network. However, jamming may also increase energy consumption and/or consume extra bandwidth, due to the transmission of the jamming signal itself.

To improve channel utilization, reducing the number of channel contentions by frame aggregation is exploited by multiple MAC protocols. Priority Unavoidable Multiple Access (PUMA) (Natkaniec and Pach 2002) is the first QoS-aware MAC protocol that uses the approach but calls it packet-train mechanism. In IEEE 802.11, this mechanism is referred to as Transmission Opportunity (TXOP) (IEEE Std 2007). The standard defines TXOP as a time interval during which a node has right to transmit frame(s) in sequence.

To increase network throughput and provide better QoS, frame manipulation is adopted in several MAC protocols. In specific, when a frame waiting in a MAC-layer queue is expired for delay violation or useless due to a loss of other dependent frame(s) at the receiver, the frame can be dropped at the transmitter side directly (Pal et al. 2002). The goal of changing frame priority is to increase the channel access probability of a specific frame, thus finishing delivery on time or before deadline (Natkaniec and Pach 2002).

If sensitive real-time traffic has periodic frames, performing channel reservation could be a good choice, to not only reduce its channel contention overhead but also guarantee its delay performance. In the literatures, channel reservation could be employed based on either Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA) or Time-Division Multiple Access (TDMA). The Multiple Access Collision Avoidance with Piggyback Reservations (MACA/PR) protocol (Lin and Gerla 1997) and the Soft Reservation Multiple Access with Priority Assignment (SRMA/PA) protocol (Ahn et al. 2000) are two of this type of typical MAC protocols, built based on CSMA/CA and TDMA, respectively.

When heterogeneous traffic, e.g., both delay-sensitive and best-effort traffic, coexist in a distributed wireless network, alternating CP and CFP provides opportunities to serve them differentially and with better QoS provisioning. In general, the Point Coordination Function (PCF) defined in IEEE 802.11 is a representative MAC protocol following this approach (IEEE Std 2007). However, PCF was designed for infrastructure network configuration, requiring

a coordinator (called the Access Point, AP) to poll other nodes for data transmission in CFP, and it suffers from preventing stations in another nearby network from transmitting competing traffic. In case of no AP available, dynamically creating the infrastructure and choosing node as the coordinator are considered in MAC protocols such as the Mobile Point Coordinator for MAC (MPC-MAC) (You et al. 2002).

Key Applications

QoS-aware MAC protocol is a fundamental component of every distributed wireless network where delay-sensitive traffic or heterogeneous traffic should be served.

Quality of Experience for wireless video streaming, which measures the quality that subjectively perceived by the end users, is able to directly and accurately reflect the subjective feelings of viewers when users watch streaming video over the wireless network.

Historical Background

Video streaming services are becoming more and more popular these days. For multimedia streaming service providers, a good video quality may lead to an increase in customer subscriptions. On the contrary, a poor video quality may result in subscriber churn. Thus, it becomes more important for the video streaming service providers to increase the user perceptual video quality. However, it is not easy to measure the user perceptual quality of a video. Classical QoS (Jin and Nahrstedt 2004) metrics in mobile networks are blocking rates for real-time traffic and average user throughput for elastic one and operators

dimension their networks for satisfying targets on those metrics.

Regarding objectively measuring the performance of a video transmission system from video server to users, QoS is considered as the most successful system quality strategy. It is widely applied in video wireless transmission system as an optimization goal. However, QoS may fail to capture the quality degradation of the viewing experience caused by factors like compression artifacts. Compared to QoS, QoE (Zhao et al. 2017), which measures the quality that subjectively perceived by the end users, is able to directly and accurately reflect the subjective feelings of the viewer.

In early works, researchers were trying to increase user perceptual video quality by appropriately selecting QoS parameters (such as video compression optimization (Sullivan and Wiegand 1998; Chen and Ngan 2007; Liu et al. 2007) and network bandwidth allocation (Chong et al. 1995; Adas 1998; Wu et al. 2001)). In Liu et al. (2007), the authors studied relationship between the peak signal-to-noise ratio and quantization parameter and propose a linear rate-quantization model to optimize quantization parameter calculation. In Wu et al. (2001), the authors presented a dynamic network resource allocation scheme for high-quality variable bitrate video transmission, based on the prediction of future traffic patterns. While monitoring and controlling QoS parameters of the video transmission system is important for achieving high video quality, it is more crucial to evaluate video quality from the users' perspective, which is known as QoE, or user-lever QoS. QoE-based video quality assessment for wireless video streaming is difficult because user experience is subjective and hard to quantify and measure. Moreover, the advent of new video compression standards, the development of video transmission systems, and the advancement of consumer video technologies all call for a newer and better understanding of user QoE. For the study of QoE, Li et al. (2018) proposed a subjective QoE metric for 360 VR video transmission over wireless networks. It makes a pixel-by-

pixel comparison between the reference content and the distorted content, producing a peak SNR figure without considering what the contents actually represent (Li et al. 2016).

In general, subjective QoE assessment tests are the most common method of studying video subjective QoE. The subjective QoE assessment method is simply that the video users watch the video in a controlled environment and use Mean Opinion Score (MOS) to score the video quality. ITU-T (Methodology for the Subjective Assessment 2002) has proposed several provisions for assessment protocol and experimental environment for subjective video quality assessment, and MOS score (Tan et al. 2016) is considered to be the most accurate reflection of video quality perception through the human visual system (HVS). The protocols for subjective video quality assessment can be generally classified into two categories: the methods of using Single Stimulus (SS) and Double Stimulus (DS). Single Stimulus (SS) method can be used when only processed videos presented to the subject. Single Stimulus Continuous Quality Scale (SSCQS) (Seshadri-nathan et al. 2010) is one of the representative Single Stimulus (SS) methods.

Unlike subjective QoE models, the study of objective QoE models does not require evaluative experiments; the relevant mathematical metrics only need to be studied. For 2D video, PSNR (or SSIM) is the most used objective QoE evaluation metric, which is based on the mean squared errors (MSE) between the reference and processed videos. However, PSNR cannot successfully reflect the subjective visual quality perceived by the human visual system (HVS) because it does not consider human visual perception at all. In order to correlate objectivity assessment with subjective quality better, many improved methods (Xu et al. 2014; Liu and Zhai 2017) based on PSNR have been proposed. Xu et al. (2014) proposed a weight-based PSNR metric to measure the quality of video. When calculating PSNR, their method imposes greater penalty weight on areas with faces and facial features. The free energy adjusted PSNR (FEA-PSNR) is proposed in Liu and Zhai (2017), which considers image perceptual complexity when evaluating

image quality. Furthermore, Na and Kim (2014) proposed a non-reference PSNR method to evaluate quantization error and the blocky effect when measuring nonreference quality of H.264 / AVC videos. Lee et al. (2016) explore the applicability of some existing objective models developed for 2D video to perceptual 3D video quality measurement.

Foundations

Researchers have studied the QoE metric for traditional single view video streaming and proposed different QoE metrics. In Oyman and Singh (2012), the recently standardized QoE metrics and reporting framework in third Generation Partnership Project (3GPP) were reviewed. The 3GPP dynamic adaptive streaming over HTTP (DASH) specification provides mechanisms for QoE measurements at the client device as well as protocols and formats for delivery of QoE reports to the network servers. Piamrat et al. (2009) focused on a hybrid QoE assessment model that retained the advantages of both subjective and objective schemes but minimized their drawbacks based on statistical learning using a random neural network (RNN).

In general, the QoE influence factors can be categorized into technical and perceptual influence factors. The perceptual influence factors are directly perceived by the end user of the application and are dependent but decoupled from the technical development. For example, several technical reasons can introduce initial delay, but the end user only perceives the waiting time. Therefore, it is necessary to analyze also the technical influence factors, which drive the perception of the end users. In general, QoE can be measured either by objective monitoring or subjective test. In video transmission system, QoE is influenced by many factors such as video capture, encoding, delivery, decoding, rendering, display, and context of use.

We give a brief introduce of the influencing factors of QoE for wireless video streaming. As shown in Fig. 1, we investigate the three major of influencing factors: initial delay, level variation, and stall.

Quality of Experience for Wireless Video Streaming, Fig. 1 The influencing factors of QoE for wireless video streaming

- *Initial Delay:* During the wireless video streaming process, there is an initial delay before the first frame of the video can be displayed, due to the need for the video client to buffer a certain amount of video data (Liu et al. 2016).
- *Level Variation:* During a video session, the video quality might keep switching. We propose three dimensions for factor level variation: (1) average level, which indicates the average quality of the entire video session; (2) number of switches, which indicates the frequency of quality switch; (3) average switch magnitude, which indicates the average amplitude of quality change.
- *Stall:* During a video session, it is possible that there is the network bandwidth fluctuation, leading to buffer underflow and stalling (rebuffering). As to the stall, most of the current research studies only consider the relationship between stall duration and QoE. However, it is obvious that the number of stalls is also vital.

Finally, QoE can be measured either by objective monitoring or subjective test. The subjective test is to obtain the quantitative representation of QoE by asking video users to grade the received video contents during the video playback in a controlled environment. It is believed to be the most accurate reflection of video quality perceived by users.

Subjective test directly measures user QoE by soliciting users' evaluation scores under the laboratory environment. Users are given a series of tested video sequences, original ones, and processed ones included and then required to give scores on the video quality. Detailed plans for conducting subjective tests have been made by the Video Quality Expert Group (VQEG) (1998). Though being viewed as a relative accurate way of measuring user QoE, subjective test suffers from three major drawbacks. First, subjective test has high cost in terms of time, money, and manual effort. Second, subjective test is conducted in the laboratory environment, with limited test video types, test conditions, and viewer demography. Therefore, the results may not be applicable to video quality assessment in the wild. Third, the subjective test cannot be used for real-time QoE evaluation.

In order to avoid high cost of subjective test, objective quality models have been developed. The major purpose is to identify the objective QoE parameters that contribute to user perceptual quality. Subjective test results are often used as ground truth to validate the performance of the objective quality models. Most of the objective quality models are based on how the Human Visual System (HVS) receives and processes the information of the video signals. One of the commonly

used methods is to quantify the difference between the original video and the distorted video, then weight the errors according to spatial and temporal features of the video. However, the need to access original video hinders online QoE monitoring. In order to develop QoE prediction models that do not depend on original videos, network statistics (such as packet loss) and spatiotemporal features extracted or estimated from the distorted video are leveraged. In the objective approach, mathematical models (algorithms) based on the human visual system are created to assess the quality of videos without external interferences. In image and video processing, PSNR is the most used objective quality assessment metric. It makes a pixel-by-pixel comparison between the reference content and the distorted content, producing a peak SNR figure without considering what the contents actually represent.

Key Application

Quality of Experience for wireless video streaming can optimize video transmission. In QoE for wireless video streaming, one of the most important aspects of studying QoE is how to improve or maximize users' overall QoE value. How to improve the experience of user is also the significance of our research of quality of experience for wireless video streaming.

Future Directions

There are some aspects that need us to research about QoE for wireless video streaming in the future. The biggest problem is that the end user's perceived instantaneous (or overall) QoE is not being objectively measured (or maximized). Although reducing the number of stalls and bitrate switches is a reasonable approach to reduce viewer annoyance, it does not capture a viewer's holistic perception of quality, nor does it guarantee the best (instantaneous or overall) QoE. A user's perceived QoE is greatly

influenced by a complex interplay of video content, varying numbers of rebuffering events, highly diverse rebuffering lengths, the rebuffering locations within a video, and so on. Therefore, having a fast and accurate objective QoE predictor that automatically predicts instantaneous quality scores that correlate well with perceived time-varying QoE could serve as feedback information that could be used to control and improve the performance of methods of quality of experience for wireless video streaming.

QoS enhancements in IEEE 802.11e; QoS provisioning in IEEE 802.11

Definitions

In order to provision quality of service (QoS) in IEEE 802.11 networks, several enhancements to the original IEEE 802.11 standard have been proposed to provide QoS services for multimedia and real-time applications over WLANs.

Historical Background

The IEEE 802.11 specification was first published in 1997 (Hiertz et al. 2010). After a

Quality of Experience (QoE) for Wireless Video Transmission

► Quality of Experience for Wireless Video Streaming

series of subsequent amendments, nowadays, it has become one of the most widely deployed wireless technologies. Traditional IEEE 802.11 standards are difficult to provide QoS services for users, due to the lack of an explicit mechanism for service differentiation. For example, the IEEE 802.11a release and also the following IEEE 802.11b and IEEE 802.11g all employ the distributed coordination function (DCF)-based schemes, in which access to the medium is given on a first-come-first-served (FCFS) basis. The FCFS mechanism could not distinguish the traffic flows with different QoS requirements; in fact, there is no notion of traffic priority, indicating no guarantee of QoS in IEEE 802.11a/b/g. This may result in performance degradation during heavy-load periods, especially in multimedia applications.

In 2005, IEEE 802.11e is released explicitly targeting at provisioning QoS solutions to IEEE 802.11 networks (IEEE 802.11e 2005). As an important extension to the traditional IEEE 802.11 standard, the IEEE 802.11e release incorporates several QoS enhancements in the media access control (MAC) layer. It improves the MAC layer for QoS provisioning in which data packets are prioritized based on their application requirements. In IEEE 802.11e, the DCF and the optional point coordination function (PCF) are combined and enhanced to a new version called hybrid coordination function (HCF).

In 2016, the most recent IEEE 802.11 release has incorporated HCF in the MAC layer (IEEE 802.11 2016).

Foundations

IEEE 802.11e enhances the MAC layer functionality by integrating HCF to provide prioritized and parameterized QoS access to the wireless medium specified by the IEEE 802.11 physical layer. HCF combines functions from the DCF and PCF in original 802.11 MAC protocols for both contention access and contention-free access. Specifically, it consists of two mechanisms for service differentiation,

namely, enhanced distributed channel access (EDCA) for contention-based channel access and HCF controlled channel access (HCCA) for contention-free traffic delivery (IEEE 802.11e 2005).

Enhanced Distributed Channel Access (EDCA)

The EDCA mechanism defines eight user priorities (values assigned for each data unit) and prioritizes traffic into four access categories (ACs), as listed in Table 1.

With EDCA, stations belonging to different ACs can contend for sending packets with different sets of parameters, including an arbitrary interframe space (AIFS), CW_{min} and CW_{max} (i.e., minimum and maximum contention window limits, respectively), and transmission opportunity (TXOP) limit. The default parameters specified by the IEEE 802.11e standard are listed in Table 2. AIFS determines the amount of time a station senses the channel to be idle before conducting backoff or transmitting packets, the contention window sizes define the bounds of random backoff periods, and TXOP limit defines the duration a station can transmit after acquiring the channel.

- *AIFS*: IEEE 802.11 employs a DCF interframe space (DIFS) for which each frame must wait until the medium is available via Clear Channel Assessment (CCA). Instead of using a constant DIFS, EDCA assigns a shorter IFS to a station with a higher priority so that it can

Quality of Service in IEEE 802.11 Networks, Table 1
Mapping between priorities and ACs

User priority	Access category (AC)	Designation
1 (lowest)	AC_BK	Background
2	AC_BK	Background
0	AC_BE	Best effort
3	AC_BE	Best effort
4	AC_VI	Video
5	AC_VI	Video
6	AC_VO	Voice
7 (highest)	AC_VO	Voice

Quality of Service in IEEE 802.11

Networks, Table 2

Default parameters in EDCA

Access category (AC)	CWmin	CWmax	AIFSN
AC_BK	aCWmin	aCWmax	7
AC_BE	aCWmin	aCWmax	3
AC_VI	$(aCWmin + 1)/2 - 1$	aCWmin	2
AC_VO	$(aCWmin + 1)/4 - 1$	$(aCWmin + 1)/2 - 1$	2

wait for less time before sending packets, implying a shorter expected delay than others with lower priorities. AIFS is decided by the access category and an arbitration interframe spacing number (AIFSN) as $AIFS[AC] = AIFSN[AC] \times aSlotTime + aSIFSTime$, where the parameter AIFSN is assigned by the AP or a management entity.

- *Contention window limits:* In EDCA, the contention window limits can be assigned distinct for different ACs. As shown in Table 2, with the default settings, ACs for heavy traffic in video and voice applications can be assigned smaller contention windows to let the corresponding stations wait less time (on average) in conducting backoff.
- *TXOP limit:* A TXOP is gained after a station succeeds in the channel access contention. It is defined by a starting time and a maximum duration, which controls the time that the station can uninterruptedly occupy the channel and transmit packets. Differentiation in the TXOP parameter can allow heavy-traffic stations to transmit multiple packets for a longer time and prevent low-load stations to occupy the channel for an unnecessarily period of time.

HCF Controlled Channel Access (HCCA)

The HCCA mechanism is developed from the point coordination function (PCF) in traditional IEEE 802.11. It makes use of a high-priority hybrid coordinator (HC), a centralized controller that collocates with the AP, to transmit packets to stations and control the channel access of them by allocating TXOPs. In order to support QoS, HCCA allows stations to request the HC for TXOPs to transmit packets to or download packets from the AP based on their own QoS demands. The HC decides whether to accept a request based on an admission control

mechanism, to be discussed below, and schedules TXOPs for the corresponding station if its request is accepted. Unlike PCF that divides a beacon interval into a control-free period (CFP) and a control period (CP), HCCA defines an additional controlled access phase (CAP) that allows the HC to reserve the channel for contention-free packet exchanges with stations that have been granted TXOPs during both CFP and CP. After the HC senses the channel to be idle for a PCF interframe space (PIFS), it transmits a packet with the duration value set to cover the CAP to claim the channel access. PIFS is smaller than DIFS and AIFS, giving the HC priority over other traffics. Therefore, a CAP may be initiated at any time, and there can be multiple CAPs within a CP. Other stations in the CP apply normal EDCA to access the channel and transmit packets.

Admission Control

The service differentiation at MAC layer is effective for QoS provisioning when network load is moderate (Malik et al. 2015). However, in situations with heavy multimedia traffic, pure service differentiation becomes inefficient and may incur long congestion delay (Zhu et al. 2004). In this case, admission control is necessary, which selectively admits traffic flows such that the QoS performance of existing flows is still ensured. There are two admission control mechanisms specified in IEEE 802.11e for contention-based access and controlled access, respectively. In the former mechanism, stations in ACs that require admission control send requests to the HC for admitting their traffic flows, while in the latter mechanism, stations request the HC for TXOPs as mentioned above (IEEE 802.11e 2005). Precise admission control is usually difficult since the accurate network status such as channel conditions, throughput, and delay may be not available. To overcome this difficulty, several methods have been pro-

posed, including measurement-based admission control based on continuously monitoring network status and model-based admission control based on some analytical or empirical models (Gao et al. 2005).

Related Work

The IEEE 802.11 standards focus on the physical and MAC layers and provide QoS support mainly in the MAC layer. On top of these layers, many QoS issues and mechanisms have been proposed such as QoS routing, congestion control, rate control, and energy-efficient QoS solutions (Peng et al. 2013; Shen et al. 2013; El Masri et al. 2014; Luo and Shyu 2011). Recently, QoS solutions can be provided within the software-defined networking (SDN) and cloud computing frameworks. For example, researchers have proposed a QoS solution called QoS Flow for OpenFlow-based SDN networks through the appropriate control of packet scheduling. In addition, OpenQoS (Egilmez et al. 2012) is an OpenFlow controller designed for supporting multimedia flows with end-to-end QoS requirements, which presents a new dynamic QoS routing scheme that maintains the shortest path for the data delivery to minimize packet loss and latency. In cloud-based wireless networks, a precise modeling of the genuine surroundings of IEEE 802.11 WLANs is important for proficient QoS-aware cloud service provisioning (Tursunova and Kim 2012). However, since these are general issues for all networks, they are not explicitly covered in this chapter.

Key Applications

QoS guarantee is a critical requirement for throughput-sensitive and delay-sensitive applications such as multimedia and real-time factory communications over WLANs.

Ginibre point process; Quality of service; Repulsive point process; Stochastic geometry; Wireless sensor network

Definitions

Quality of service (QoS) indicates the description of the performance of a service which is influenced by various features such as throughput, errors, and latency. Wireless sensor network (WSN) is a network consisting of spatially distributed sensor nodes which monitor and report physical or environmental conditions. Ginibre point process (GPP) is a point process which can consider repulsion among the locations of the points in the point process.

Historical Background

Mathematically analyzing QoS of wireless networks helps us to obtain insights on the impacts of systems parameters on the QoS. Recently, stochastic geometry has been widely used as a tool for modeling wireless networks and analyzing QoS of the networks (Haenggi 2012). Due to its simplicity, the Poisson point process (PPP), whose the locations of the points are independent,

has been applied to various wireless networks such as ad hoc wireless networks (Weber et al. 2007), cellular networks (Dhillon et al. 2012), and wireless energy harvesting networks (Sakr and Hossain 2015).

In practical networks, the locations of transmitters may not be placed close to each other in order to mitigate interference and extend coverage region (Lin et al. 2015). In this context, determinantal point processes (DPPs) (Li et al. 2015) which can consider this repulsive nature have gained a lot of attention as a model for wireless networks. The GPP is one example of the DPP (Decreusefond et al. 2015). The α -GPP ($-1 \leq \alpha < 0$) is a DPP which contains the GPP ($\alpha = -1$) and the PPP ($\alpha \rightarrow 0$) as special cases. In the α -GPP, the parameter α (termed *repulsion parameter*) represents the degree of the repulsion among the points, and the strength of the repulsion grows as α decreases. In Kong et al. (2016), the performance of ambient wireless energy harvesting networks was investigated by adopting the α -GPP.

QoS Analysis

Fundamental Properties of the α -GPP

$B(r)$ denotes a ball centered at the origin with radius r . Then, for an α -GPP Φ on an observation window $W = B(R)$ with intensity λ , the hole probability is given by

$$Pr(\Phi \cap B(r) = \emptyset) = Pr(\forall x \in \Phi, \|x\| > r) \\ = \prod_{n \geq 0} \left(1 + \alpha \frac{\gamma(n+1, \pi \lambda r^2)}{n!} \right)^{-1/\alpha}, \quad (1)$$

where $\gamma(a, b) = \int_0^b t^{a-1} e^{-t} dt$ is the lower incomplete gamma function. Also, for a non-negative function q , the Laplace transform is expressed as

$$E \left[\exp \left(- \sum_{x \in \Phi} q(x) \right) \right] = \prod_{n \geq 0} (1 + \alpha v_n)^{-1/\alpha}, \quad (2)$$

where

$$v_n = \frac{2(\pi\lambda)^{n+1}}{n!} \int_0^R (1 - \exp(-q(x))) \exp(-\pi\lambda r^2) r^{2n+1} dr.$$

System Model

WSNs are composed of a number of gateways and sensor nodes. It is assumed that each sensor node is connected to the closest gateway. In order to consider a repulsive nature in the WSNs, the spatial distributions of the gateways and the sensor nodes are modeled by independent α -GPPs Φ_g and Φ_s with intensities λ_g and λ_s and repulsion parameters α_g and α_s , respectively.

On a given resource block, a single sensor node is associated with the nearest gateway, and therefore for a sensor node located at y , the association rule can be expressed as

$$\begin{aligned} x^o &= \arg \min_{x \in \Phi_g} \|x - y\|, \\ d &= \min_{x \in \Phi_g} \|x - y\|, \end{aligned} \quad (3)$$

where x^o denotes the location of the associated gateway. In order to alleviate interference, sensor nodes employ a fractional channel inversion power control. More specifically, the transmit power at a sensor node at y is

$$P = \tau d^\epsilon, \quad (4)$$

where τ and $\epsilon \in [0, 1]$ indicate the receiver sensitivity and the power control factor, respectively.

The throughput of a link is related to the signal-to-interference-plus-noise ratio (*SINR*) of the link. Therefore, the *SINR* outage probability is one of the most widely used QoS metrics.

From the stationarity of the α -GPP, without loss of generality, it is assumed that the gateway serving a typical sensor node (termed *tagged gateway*) is located at the origin. Then, the *SINR* outage probability at the tagged gateway is given by

$$P_{\text{out}} = \Pr(\text{SINR} < \gamma_{th}), \quad (5)$$

where

$$\text{SINR} = \frac{\tau h_0 \|x_0\|^{l(\epsilon-1)}}{\sum_{x \in \Phi_I} P_x h_x \|x\|^{-l} + \sigma^2}. \quad (6)$$

Here, h_0 , l , and σ^2 denote the power of the fading channel between the tagged gateway and the typical sensor node, the path loss exponent, and the power of the additive white Gaussian noise, respectively. Φ_I is a point process which presents the spatial distribution of the interfering sensor nodes. Also, x_0 , P_x , and h_x are the location of the typical sensor node, the transmit power at the sensor node at x , and the power of the fading channel between the tagged gateway and interfering sensor at x . It is assumed that fading channels follow the Rayleigh distribution, and hence h_0 and $\{h_x\}$ follow i.i.d. exponential distribution with unit mean.

Outage Probability

As seen in (5), the *SINR* outage probability is related to both the distances between sensor nodes and their serving gateways and the transmit powers at sensor nodes.

Theorem 1 *The cumulative distribution function (CDF) and the probability density function (PDF) of d in (3) are, respectively, given by*

$$F_d(r) = \Pr(d \leq r) = 1 - \prod_{n \geq 0} \left(1 + \alpha_g \frac{\gamma(n+1, \pi\lambda_g r^2)}{n!} \right)^{-1/\alpha_g}, \quad (7)$$

$$\begin{aligned} f_d(r) &= 2 \exp(-\pi\lambda_g r^2) (1 - F_d(r)) \\ &\quad \times \sum_{n \geq 0} \frac{1}{n!} (\pi\lambda_g)^{n+1} r^{2n+1} \left(1 + \alpha_g \frac{\gamma(n+1, \pi\lambda_g r^2)}{n!} \right)^{-1}. \end{aligned} \quad (8)$$

Proof. The CDF in (7) can be derived from (1), and the PDF in (8) can be obtained by differentiating the CDF in (7) with respect to r . $\square$

Theorem 2 The CDF and the PDF of P in (4) are, respectively, given by

$$F_P(p) = 1 - \prod_{n \geq 0} \left(1 + \alpha_g \frac{\gamma(n+1, \pi \lambda_g p^{\frac{2}{\varepsilon l}} \tau^{-\frac{2}{\varepsilon l}})}{n!} \right)^{-1/\alpha_g}, \quad (9)$$

$$f_P(p) = \frac{2}{\varepsilon l} \exp\left(-\pi \lambda_g p^{\frac{2}{\varepsilon l}} \tau^{-\frac{2}{\varepsilon l}}\right) (1 - F_P(p)) \sum_{n \geq 0} \frac{1}{n!} \left(\pi \lambda_g \tau^{-\frac{2}{\varepsilon l}}\right)^{n+1} \\ \times p^{\frac{2}{\varepsilon l}(n+1)-1} \left(1 + \alpha_g \frac{\gamma\left(n+1, \pi \lambda_g p^{\frac{2}{\varepsilon l}} \tau^{-\frac{2}{\varepsilon l}}\right)}{n!} \right)^{-1}.$$

Proof. The CDF in (9) can be identified from (1) and (4). In addition, the PDF in (10) can be derived by differentiating the CDF in (9) with respect to p . $\square$

From the CDFs in (7) and (9), it is shown that the CDFs are decreasing functions of α_g since $\alpha_g < 0$. Therefore, for a given sensor node, the distance between the sensor node and its serving gateway and the transmit power at the sensor node get higher as the degree of the repulsion among gateways decays (i.e., α_g increases). In this context, from the expression of the SINR in (6), it is expected that the SINR outage probability P_{out} is an increasing function

of α_g since an increase in α_g leads to an increase of $\|x_0\|$ and P_x .

In order to obtain an exact expression of P_{out} in (5), the distribution of Φ_I should be identified. However, the distribution is still unknown. Since a single sensor node is associated with a gateway at a given resource block, the intensity of Φ_I is equal to λ_g . Motivated by the fact, Φ_I can be approximated by an α -GPP with intensity λ_g and repulsion parameter $\alpha_s \tilde{\Phi}_I$. Then, an approximation of P_{out} in (5) can be derived as presented in the following theorem.

Theorem 3 An approximation of the SINR outage probability P_{out} in (5) is given by

$$P_{\text{out}} \approx 1 - \int_0^\infty \exp\left(-\frac{\gamma_{th} \sigma^2}{\tau u^{l(\varepsilon-1)}}\right) K(u) f_d(u) du, \quad (11)$$

$$K(u) = \prod_{n \geq 0} \left(1 + \frac{2\alpha_s (\pi \lambda_g)^{n+1}}{n!} \right. \\ \left. \times \int_0^\infty \int_{\left(\frac{p}{\tau u^{l(\varepsilon-1)}}\right)^{\frac{1}{l}}}^R \exp\left(-\pi \lambda_g r^2\right) \frac{1}{1 + \tau r^l u^{l(\varepsilon-1)}/(\gamma_{th} p)} r^{2n+1} dr f_P(p) dp \right)^{-1/\alpha_s}.$$

Quality of Service of Wireless Sensor Networks Modeled by Ginibre Point Processes,

Fig. 1 SINR outage probability as a function of γ_{th} when Φ_s is a PPP ($\alpha_s \rightarrow 0$), $\lambda_g = 4$ gateways/km², $\sigma^2 = -90$ dBm, $R = 5$ km, and $l = 4$

Proof. Since h_0 is an exponential random variable with unit mean,

$$P_{\text{out}} = \Pr \left(h_0 < \frac{\gamma_{th}}{\tau \|x_0\|^{l(\epsilon-1)}} (I + \sigma^2) \right) \\ = 1 - \int_0^\infty \exp \left(-\frac{\gamma_{th} \sigma^2}{\tau u^{l(\epsilon-1)}} \right) L_I \left(\frac{\gamma_{th}}{\tau u^{l(\epsilon-1)}} \right) f_d(u) du, \quad (12)$$

where $I = \sum_{x \in \Phi_I} P_x h_x \|x\|^{-l}$ and $L_X(s) = E[e^{-sX}]$ denote the Laplace transform of a random variable X . Then, by approximating the distribution of interferers as $\tilde{\Phi}_I$ and by applying the formula in (2), an approximation of P_{out} can be obtained as in (11). For the details, please refer to Kong et al. (2017). $\square$

From Fig. 1, it is observed that the approximation in (11) shows almost identical performance with the simulated results. Note that a higher α_g results in higher transmit powers at sensor nodes and P_{out} is an increasing function of α_g . Therefore, it is concluded that QoS of WSNs can be improved with lower transmit powers when there exists repulsion among the locations of the gateways.

Definitions

Physical layer identification (PLI) is the user device identification strategy based on the physical features of the wireless device. Radio-frequency fingerprinting is one of the most important PLI techniques that utilize the uniqueness in the waveform of the wireless signals emitted by the device to be identified.

Background

The wireless access to restricted networks, such as in enterprise or government, can grant great convenience and efficiency to the employees and visitors. However, the broadcasting nature of wireless communications brings significant secure risks, especially in the networks with sensitive data. Without the binding of wired connections, it is much easier for adversary to obtain security credentials from legitimate users through the wireless channel. Therefore, it is important to authenticate users not only by what they hold (e.g., logical level ID or pre-shared key) but also by what they are, i.e., identifying the wireless device itself based on various physical layer device features. Such device identification technique is defined as physical layer identification (PLI). PLI is a promising built-in secure access control solution that authenticates the device based on its inherent features. PLI can guarantee only authenticated devices access the network and can enhance the cryptography-based security protocols to authenticate users themselves.

PLI is not a single technique but a wide variety of user device identification techniques based on different physical features, including (i) the image artifacts in a photos taken by the camera of the user device, (ii) the response of the audio circuit to a predefined stimulus (e.g., a standard tone), (iii) the RF emissions from LCD screens, (iv) the measurement distortion caused by the MEMS in accelerometers or magnetome-

ters, and (v) the multipath effects added to signals when propagating through the wireless channel, among others. In this entry, we focus on one of the PLI techniques that we believe has the widest applicable range, i.e., the radio-frequency fingerprinting (RFF)-based PLI. RFF-based PLI identifies the user device based on any features extracted from the waveforms of the wireless signals, i.e., the electromagnetic waves that are radiated by the device to be tested. While the conventional software-level device identifications (e.g., IP or MAC address) can be easily changed by malwares, the RFF features cannot be modified without significant effort. Moreover, different from the other PLI techniques that either rely on the features from particular hardware not existing in any types of devices (e.g., camera, audio circuit, LCD, and accelerometers) or require the target device fixed in one location (e.g., multipath effects), the RFF features exist in any wireless device as long as it uses radio for communication and allow the user mobility. Therefore, the RFF-based technique is deemed as a promising wireless security solution.

In this entry, the sources of RFFs and the mechanisms to utilize such RFFs in the state-of-the-art RFF-based PLI techniques are explained through each step in the physical layer procedures in wireless communications.

Foundations

In essence, RFFs are random variables carrying discriminating information of user identity which

can be expressed in different feature domains, such as frequency domain, time domain, wavelet transform domain, etc. Figure 1 illustrates the logic procedure of RFF-based PLI during the wireless communication between a transmitter (the device to be identified) and a receiver (the identifier). The RFFs can come from many points along that procedure. At the transmitter side, the RFFs are rooted in the hardware imperfections of the transmitter device (Danev et al. 2012), which include clock jitter (Zanetti et al. 2010; Jana and Kasera 2010), the DAC sampling error (Polak et al. 2011), the mixer or local frequency synthesizer (Toonstra and Kinsner 1996, 1995), the power amplifier nonlinearity (Polak et al. 2011, Polak and Goeckel 2011; Liu and Doherty 2008), device antenna (Danev et al. 2009), and modulator sub-circuit (if the analog modulation is used) (Brik et al. 2008), among others. The EM waves stamped with the hardware-imperfection-based RFFs are then radiated by the transmitter antenna to the wireless channel, where the multipath effects of the wireless link can be also used as physical layer feature to identify user devices (Li et al. 2006; Xiao et al. 2007). However, the wireless channel-based physical layer feature only works when the user devices are fixed, while the RFF features support user mobility. At the receiver (i.e., the identifier), the RFF-stamped signals are received by the receiver antenna and processed through the analog circuits and digital processing units. Depending on their properties, different RFFs are extracted at (i) different parts of the signals, such as turn-on/off transient (Toonstra and Kinsner

Radio-Frequency Fingerprinting-Based Physical Layer Identification, Fig. 1 RFF-based PLI procedure along wireless communication flow block diagram

1995; Danev and Capkun 2009; Rehman et al. 2012a; Hall et al. 2004), data (Zanetti et al. 2010; Danev et al. 2009; Suski et al. 2008; Klein et al. 2009; Rehman et al. 2012b), and clock (Zanetti et al. 2010; Jana and Kasera 2010), and (ii) different domains, such as time (Brik et al. 2008), frequency (Danev et al. 2009; Danev and Capkun 2009), and wavelet domains (Brik et al. 2008). Finally, the extracted RFF is matched with the fingerprint database, which complete the physical layer identification process.

In the following sections, the complete RFF-based PLI procedure is systematically discussed in details. As shown in Fig. 1, the RFF-based PLI is closely coupled with wireless communications, including four major segments: the signal processing and RFF stamping at the transmitter, the signal propagation along wireless channels, the signal reception and feature extraction at the receiver, and the final identification and classification.

Signal Processing and RFF Stamping at Transmitter

At the beginning of the signal processing at the transmitter, the data source sends binary bits sequence to the digital modulation block, where the sequential binary bits are first mapped to higher-order and complex transmit symbols. We use m to index the sequence of the transmitted symbols so that each symbol is denoted as $x_m = x_m^I + j x_m^Q$, where x_m^I and x_m^Q are the in-phase and quadrature components, respectively. The duration of each symbol is determined by the expected data rate and the order of modulation scheme, which is denoted as T_{symbol} . Ideally, T_{symbol} should be a constant in one packet transmission. However, due to the clock-related hardware imperfection, the period/duration of each symbol can vary. As a result, the first possible RFF due to the hardware imperfection appears, which is regarded as a unique time domain feature and is defined as time interval error (TIE) (Zanetti et al. 2010). We denote this feature as σ_{TIE}^m at the m th symbol. Hence, the real symbol duration of the m th symbol becomes $T_m = T + \sigma_{TIE}^m$.

After that the complex symbols x_m is processed by the shaping filter $h_s(t, T_m)$, which gives the output $b_{\text{mod}}(x_m, h_s(t, T_m))$, where the formulation of the function $b_{\text{mod}}(\cdot)$ is determined by the specific modulation scheme. Then the digital signal moves to the digital-to-analog converter (DAC). It should be noted that $b_{\text{mod}}(x_m, h_s(t, T_m))$ is in fact a discrete function as the digital shaping filter $h_s(t)$ only changes value when the DAC generates new output. We consider that the DAC has a generation period T_g , i.e., the DAC converts the value of $b_{\text{mod}}(x_m, h_s(t, T_m))$ to analog current every T_g second. Then the input digital signal $u[n]$ (indexed by n) at the DAC can be expressed as

$$u[n] = A \sum_m b_{\text{mod}}(x_m, h_s(nT_g - mT_m, T_m)), \quad (1)$$

where A is the amplitude coefficient. It should be noted that the clock-related hardware imperfection could also influence the DAC generation period T_g . However, since T_g is much smaller than T_m (due to the high DAC sampling rate), the TIE in T_g is much less significant and can be neglected. It is also worth mentioning that any specific wireless protocol (e.g., 802.11, 802.15, GSM/GPRS, etc.) defines particular modulation schemes and shaping filter, which prepare the transmitted signal with different bandwidth and power spectrum density (PSD). Those parameters can dramatically influence the significance of RFF and eventually affect the performance of RFF-based PLI.

Ideally, the DAC converts the baseband signal sequence $u[n]$ to a time-continuous analog signal $u(t)$. However, the real output signal $y_u(t)$ from practical DAC is combed with quantization error and integral nonlinearity (INL) (D'Apuzzo et al. 2010), which can be expressed as

$$y_u(t) = \sum_{n=-\infty}^{\infty} (u(n) + \Delta_n) g\left(\frac{t - nT_g}{T_g}\right) + \Delta_{\text{INL}},$$

$$g(\theta) = \begin{cases} 1, & 0 \leq \theta < 1 \\ 0, & \text{elsewhere} \end{cases} \quad (2)$$

where Δ_n is quantization noise (for M-bit DAC quantization with input signal dynamic range $[-U, U]$, the maximum quantization error is $\delta_\Delta = 2^{-M} U$) and Δ_{INL} is the integral nonlinearity that is also regarded as a unique feature rooted in hardware imperfection in Polak et al. (2011).

After the DAC, the analog baseband signal is moved to passband by the mixer. Ideally, the complex passband signal $z(t)$ consists the in-phase component $i(t) \cdot \cos(\omega_c t)$ and the quadrature component $jq(t) \cdot \sin(\omega_c t)$, where ω_c is the carrier angle frequency and $i(t) = \text{Re}\{y_u(t)\}$, $q(t) = \text{Im}\{y_u(t)\}$. However, in practical, the phase offset quadrature error occurs in this procedure due to the imperfection of transmitter's frequency synthesizers (local oscillators), which modifies $z(t)$ to

$$\begin{aligned} z(t) = & \frac{1}{2} \left(\text{Re}\{y_u(t)\} \cdot e^{j\zeta/2} \right. \\ & \left. + \text{Im}\{y_u(t)\} \cdot e^{-j\zeta/2} \right) \cdot e^{j\omega_c t} \\ & + \frac{1}{2} \left(\text{Re}\{y_u(t)\} \cdot e^{j\zeta/2} \right. \\ & \left. - \text{Im}\{y_u(t)\} \cdot e^{-j\zeta/2} \right) \cdot e^{-j\omega_c t} \end{aligned} \quad (3)$$

where ζ is the quadrature error. In Toonstra and Kinsner (1995, 1996), the uniqueness of the mixer quadrature error is utilized as RFFs.

Finally, the passband signals go through the TX front-end amplifier and filter to gain enough power for radiation. In this procedure, another important RFF is stamped, i.e., the nonlinearity of the front-end amplifier (Gharaibeh 2011), which is widely used in many recent RFF-based PLI techniques (Gharaibeh 2011; Polak et al. 2011; Polak and Goeckel 2011; Liu and Doherty 2008). The output signal can be formulated as

$$\begin{aligned} w(t) &= h_{PA}(z(t), \tilde{\mathbf{a}}_{\text{tx}}) \otimes h_{BP}(t) \\ H_{BP}(f) &= \begin{cases} 1, & |f| < W_c \\ 0, & |f| > W_c \end{cases} \end{aligned} \quad (4)$$

where $h_{PA}(\cdot, \tilde{\mathbf{a}}_{\text{tx}})$ is nonlinear function of power amplifier at the transmitter, $\tilde{\mathbf{a}}_{\text{tx}}$ is complex power series, $\otimes$ stands for convolution computing, and

$h_{BP}(t)$ is the band-pass filter function that is nearly ideal within the carrier bandwidth W_c .

Signal Propagation Between TX and RX Antennas Along Wireless Channel

We consider the antennas as part of the wireless channel since both the antenna polarization and the multipath channel can be used as RFFs. With the input signal $w(t)$ given in (4), the intensity of the radiated EM waves by a polarized antenna is given by

$$\begin{aligned} \mathbf{A}_{tx}(t) &= F_{tx}^h[w(t)] \cdot e^{-j\phi_{tx}^h} \cdot \rho_h \\ &+ F_{tx}^v \cdot \rho_h + F_{tx}^v[w(t)] \cdot e^{-j\phi_{tx}^v} \cdot \rho_v \end{aligned} \quad (5)$$

where ρ_h and ρ_v are the direction unit vectors in the horizontal and vertical directions, respectively; $F_{tx}^h(\cdot)$ and $F_{tx}^v(\cdot)$ are the TX antenna projection functions that project the input signal $w(t)$ to the horizontal and vertical polarization, respectively; and ϕ_{tx}^h and ϕ_{tx}^v are the polarization phases at both directions. In some specific wireless system, such as RFID using the spiral coil antenna, the imperfection of antenna hardware can also contribute to the RFF (Danev et al. 2009). Moreover, even for the simpler antennas that are widely used in contemporary wireless devices (e.g., dipole antennas and patch antennas), although the RFF does not come from antenna imperfection, the random direction of antenna can generate random polarization. Then the antenna polarization can either influence the RFFs due to other hardwares (Danev and Capkun 2009) or act as a new RFF (coupled with the multipath effect) (Li et al. 2006; Xiao et al. 2007).

The radiated EM waves then propagate through the multipath wireless channel and finally reach the RX antenna at the receiver. As the RX antenna can be also polarized, the intensity of the EM waves at the RX antenna is also presented in both horizontal and vertical direction:

$$\mathbf{A}_{rx}(t) = \sum_{i=1}^{N_p} \mathbf{A}_{tx}(t) \cdot \left(h_i^h \cdot \rho_h + h_i^v \cdot \rho_v \right) \quad (6)$$

$$\otimes \delta(t - \tau_i)$$

where we consider there are N_p paths (including line-of-sight, reflected, diffracted, and refracted paths) connecting the transmitter and receiver; h_i^h and h_i^v are the path loss of the i th path with horizontal polarized waves and vertical polarized waves, respectively; and τ_i is the propagation delay of the i th path.

It is obvious that the complex multipath wireless channel can arbitrarily change the amplitude, the delay, and the phase of the EM waves at each single path. Consequently, the wireless channel can literally mask most, if not all, RFFs stamped at the transmitter. Hence, the channel effects on PLI need special attention in the performance evaluation. In Danev and Capkun (2009) and Danev et al. (2012), it has been proved that the PLI accuracy decreases as the distance between the transmitter and receiver increases. It should be noted that the channels considered in Danev and Capkun (2009) and Danev et al. (2012) are still friendly, which is open space without significant multipath and obstructions. The practical wireless channel, especially in real indoor or metropolitan environments, could be much more hostile in keeping the RFFs from the transmitter.

It should be also noted that another branch of PLI systems uses the multipath channel characteristics to authenticate the transmitter (mainly its location) (Li et al. 2006; Xiao et al. 2007). The obvious drawback is that such system only works when the transmitter and receiver are fixed and there should be no mobile obstructions in the environment that can change the channel characteristics. However, those conditions are not feasible in most current wireless applications.

Signal Reception and Processing at Receiver

At the receiver, the RX antenna captures the EM waves (given in (6)) and converts both the

horizontal and vertical polarized components to the received signal:

$$r(t) = F_{rx}^h{}^{-1} \left[\mathbf{A}_{rx}(t) \cdot \rho_h \cdot e^{j\phi_{rx}^h} \right] \quad (7)$$

$$+ F_{rx}^v{}^{-1} \left[\mathbf{A}_{rx}(t) \cdot \rho_v \cdot e^{j\phi_{rx}^v} \right];$$

where $F_{rx}^h(\cdot)^{-1}$ and $F_{rx}^v(\cdot)^{-1}$ are the RX antenna functions that capture the horizontal and vertical EM wave components, respectively, and ϕ_{rx}^h and ϕ_{rx}^v are the polarization phases of the RX antenna.

Similar as the transmitter, the received signal also needs to pass through the RF front-end at the receiver:

$$f(t) = h_{PA}(r(t) \otimes h_{BP}(t), \tilde{\mathbf{a}}_{rx}) \quad (8)$$

where $h_{PA}(\cdot, \tilde{\mathbf{a}}_{rx})$ is nonlinear function of power amplifier at the receiver and $h_{BP}(t)$ is the band-pass filter at the receiver, all similar to the case at the transmitter.

Then the output signal from the RX front-end is converted to baseband by the receiver mixer with quadrature errors (i.e., carrier demodulation). The demodulation signal then goes through the low-pass filter $h_{LP}(t)$ to eliminate the higher-frequency components, which gives the results of

$$x(t) = \frac{1}{2} \left(\text{Re}\{f(t)\} \cdot e^{j\zeta/2} \right. \quad (9)$$

$$+ \text{Im}\{f(t)\} \cdot e^{-j\zeta/2} \Big) \cdot e^{j\omega_c t} \otimes h_{LP}(t)$$

$$+ \frac{1}{2} \left(\text{Re}\{f(t)\} \cdot e^{j\zeta/2} \right.$$

$$- \text{Im}\{f(t)\} \cdot e^{-j\zeta/2} \Big) \cdot e^{-j\omega_c t} \otimes h_{LP}(t)$$

Note that the low-pass filter at the receiver always has a strict cutoff to control the noise level. The gains of the passband and stopband can significantly affect the extracted RFFs, especially the spectrum-domain RFFs. The low-pass filter function $h_{LP}(t)$ can be modeled as

$$H_{LP}(f) = \begin{cases} A_p, & |f| < W \\ A_s, & |f| > W \end{cases} \quad (10)$$

where A_p and A_s are the gains in the passband and stopband, respectively.

Finally, the received baseband signals $x(t)$ are sampled by analog-to-digital converter (ADC) to obtain the digital signal sequences which are sent to the identification units to extract the fingerprints. The ADC output is expressed as

$$x[n] = x(nT_s) + \Delta_n \quad (11)$$

where Δ_n is random quantization noise; for M-bit ADC quantization and input dynamic range $[-V, V]$, the maximum quantization error is $\delta_\Delta = 2^{-M} V$. Most existing RFF-based PLI solutions utilize the high-end measurement equipment (e.g., oscilloscope and spectrum analyzer) as the receiver. The key difference between the real wireless receivers lies in the sampling rate. While the oscilloscope and spectrum analyzer can directly sample the passband (or the baseband) signal at sampling rate in the order of GHz, most practical wireless device can only sample the baseband signal at the MHz rate.

It should be noted that the above signal reception and processing procedures are also subject to the influence of the hardware imperfections at the receiver's antenna, front-end, mixer, and ADC. However, those hardware imperfections are known to the receiver (or the identifier). Hence, the deviation or errors introduced by those hardware imperfections at the receiver can be adjusted and corrected when RFF is extracted.

RFF Extraction, Identification, and Classification

At the identification unit of the receiver, the RFFs are extracted from the sampled digital signals (The exception is the RFFs residing in the passband turn-on/off transient, which is digital sampled and extracted right after the RX front-end. Our model can be easily adjusted to describe such case by deleting the signal processing of mixer.) ($x[n]$ in (11)). The extracted feature can be expressed as

$$\mathbf{S} = \text{Feature}(\{x[n], n \in \mathbf{N}\}) \quad (12)$$

where $\mathbf{N}$ is the set of all sampled digital signals in this round of identification and $\text{Feature}(\cdot)$ is the feature extraction function. Depending on the properties of the RFF and the selected extraction strategy, the feature extraction function $\text{Feature}(\cdot)$ usually consists of domain change (e.g., Fourier transform, wavelet transform, and Hilbert transform, among others) and dimensionality reduction (e.g., linear discriminant analysis (LDA), principal component analysis (PCA), or simply picking us a certain parameter such as modulation errors and phase errors).

By now, the RFF $\mathbf{S}$ is obtained. The next step is to match the RFF with the reference fingerprint, $\mathbf{S}_R$, to calculate the distance matching scores and make the classification or identification decisions. The performance of the classification/identification can be evaluated by the error probabilities, which can be theoretically calculated through hypothesis testing models.

Classification

For N-users classification scenario, the N-hypothesis testing techniques can be adopted to apply to N genuine users with M_N reference fingerprints in the database for each user (Levine and Khuon 1992). The hypothesis $\mathcal{H}_N$ is that the obtained signal is from the genuine user $\#N$. Then the classification probability can be expressed by $P(\mathcal{H}_i | \mathcal{H}_j)$, $i, j = 1, \dots, N, i \neq j$, which is the probability that the RFF from genuine user $\#j$ is classified as the genuine user $\#i$. Such probability can be derived based on the feature distance between the extracted testing feature vector $\mathbf{S}$ with the reference feature vector $\mathbf{S}_R$:

$$D_i(\mathbf{S}) = \text{Distance}(\mathbf{S}, \mathbf{S}_R) \quad (13)$$

The testing feature vector $\mathbf{S}$ is matched with all the reference fingerprints and assigned to the identity with the smallest distance score. Then the classification error probability can be expressed as

$$P(\mathcal{H}_i | \mathcal{H}_j) = P(D_i = \min(\{D\}) | \mathcal{H}_j); \quad (14)$$

where the formulation of the probability $P(D_i = \min(\{D\}) | \mathcal{H}_j)$ depends on the distribution of $D_i(\mathbf{S})$. Then the average classification error rate can be derived:

$$P_e = \sum_{i=1}^N \sum_{j=1, j \neq i}^N P(\mathcal{H}_j | \mathcal{H}_i) P(\mathcal{H}_i) \quad (15)$$

Identification

Unlike the N -users classification, in the identification procedure, the distance scores between each authorized class are not the key metric. The whole network can be considered as a two-user hypothesis model (Danev and Capkun 2009; Polak et al. 2011; Polak and Goeckel 2011). $\mathcal{H}_1$ is the hypothesis that the incoming testing fingerprint is from the genuine users, while $\mathcal{H}_0$ indicates that the testing fingerprint is from an unknown imposter. In another word, all the N genuine users that have reference fingerprints stored in database can be treated as a whole class. A decision threshold λ is set up based on the calculated feature distance. If the minimal distance score is larger than the threshold, the testing feature is identified as an imposter's fingerprint, i.e., $\mathcal{H}_0$; otherwise it is judged as from a genuine user $\mathcal{H}_1$, i.e.,

$$\min(\{D\}) \underset{\mathcal{H}_1}{\overset{\mathcal{H}_0}{\geq}} \lambda. \quad (16)$$

To evaluate the accuracy of identification performance, several probability metrics can be applied (Danev et al. 2009; Danev and Capkun 2009), including false accept rate (FAR) $P(\mathcal{H}_1 | \mathcal{H}_0)$, false reject rate (FRR) $P(\mathcal{H}_0 | \mathcal{H}_1)$, genuine accept rate (GAR) $P(\mathcal{H}_1 | \mathcal{H}_1)$, and genuine reject rate (GRR) $P(\mathcal{H}_0 | \mathcal{H}_0)$. Based on the decision rule given in (16), the above probabilities can be calculated in the same way as the classification case according to (13) and (14). We don't further elaborate the similar formulas here. To generate a single probability metric in identification system, many work put the above error rates together in the receiver operating characteristic (ROC) chart where the FRRs (or GARs) are plotted as a function of different FAR

levels. The operating point in ROC, where FAR and FRR are equal, is referred to as the equal error rate (EER).

Summary

The radio-frequency fingerprinting (RFF)-based physical layer identification (PLI) is a promising user device identification technique based on the inherent features from signal waveforms. In this entry, we rigorously model and discuss the sources of RFFs and device identification mechanisms along every single step in the RFF-based PLI techniques. The theoretical model provides the systematical description on the whole RFF-based PLI procedure, which is applicable in most state-of-the-art PLI techniques that are based on digital wireless communications.

Synonyms

On-demand WLAN; Wake-on-wireless; Wake-on-WLAN; Wake-up control of WLAN

Definitions

Radio-on-demand wireless LAN (WLAN) defines a WLAN where each node (a power-hungry WLAN module) wakes up to communicate under a request, that is, each node is equipped with a low-power wake-up radio (WuR), which receives a wake-up message and activates its co-located WLAN module on demand.

Historical Background

Radio-on-demand WLAN realizes the wake-up control of a WLAN module. This function becomes urgent because nowadays WLAN modules are widely embedded into mobile devices (such as smartphones) driven by batteries with limited capacity.

A WLAN module can have different states with different power consumptions, as shown in

Table 1. The power relationship usually is Transmitting > Receiving > Idle > Transition > Sleep > Power-off. Without any power-save mechanism, a WLAN module is in the continuously awake mode (Idle, Receiving, or Transmitting). Analysis of traffic statistics indicates that WLAN traffic is bursty. A WLAN module is in the Idle state during most time, but its idle listening leads to much energy waste.

Power consumption of a WLAN module is highly related to the media access control (MAC) protocol design (Liu et al. 2018), and duty-cycling is a conventional method to this problem. In WLAN, duty-cycling is realized as the power-save mode. Each node periodically wakes up to receive traffic indication information from its associated access point (AP), by setting up a wake-up timer before entering the sleep state. But power consumption in the sleep state is non-negligible because some part like memory is still running, and periodical wake-up (transition from Sleep to an active state and vice versa) also causes much energy overhead. In the power-save mode, the longer a node sleeps, the more it saves power, but at the cost of a larger latency, which degrades quality of service (QoS).

To achieve both a long sleep and a fast response, an aggressive method is to completely turn off a WLAN module in its idleness to the Power-off state and activate it on demand. The remote wake-up control of a WLAN module from the Power-off state uses an out-of-band mechanism, which requires the cooperation between a sender and its target receiver. This was initially implemented and evaluated in Shih

et al. (2002), where an IEEE 802.15.4 radio is used as a WuR for the wake-up control of an IEEE 802.11b module. After a few years of research and development, currently, IEEE 802.11ba standards task group is working on an amendment of wake-up radio to enable low-power and low-latency WLANs (McCormick 2017). It should be noted that remote wake-up control alone is not always sufficient. A more aggressive policy is to harvest ambient energy to charge each node as well (Li et al. 2018).

Foundations

A WLAN module in the Idle state performs carrier sense for future channel access or receives packet headers to detect potential incoming packets. It consumes almost the same power as in the Receiving state. A WLAN module typically uses the same transceiver for both the control and data communications. In addition, power consumption of a WLAN transceiver increases with the supported data rate and the number of antennas. The control plane actually has little traffic, which does not require a high data rate. Therefore, it is necessary to separate the control plane from the data plane, at least in the wake-up control.

The key point of wake-up control is to equip each node with a low-power WuR for the wake-up signaling (at a low transmission rate), as shown in Fig. 1. A WuR can be implemented by different methods. (i) A generic low-power device, such as ZigBee or Bluetooth low energy (BLE), etc., can be used as a WuR (Shih et al.

Radio-on-Demand Wireless LAN, Table 1 States of a WLAN module

State	Meaning of the state
Power-off	A WLAN module is completely turned off, and its power consumption is nearly zero
Sleep	Although most part of a WLAN module is turned off, its memory (holding the associating state, etc.) is still working, whose power consumption is non-negligible
Transition	A WLAN module transits from the Sleep or Power-off state to an active state or vice versa
Idle	A WLAN module is active, but is neither transmitting a packet to others nor receiving a packet destined to itself. But it may overhear packets destined to other nodes
Receiving	A WLAN module is receiving a packet destined to itself
Transmitting	A WLAN module is transmitting a packet to other nodes

Radio-on-Demand Wireless LAN, Fig. 1

Integration of a wake-up radio with a WLAN module

2002). (ii) A specific device can be designed to only realize the wake-up function, whose power consumption can be reduced to be very low (Demirkol et al. 2009). A wake-up message is usually transmitted by the simple on-off-keying (OOK) and is received by envelope detection instead of coherent detection. In these methods, wake-up messages and WLAN signals are transmitted over different channels to avoid mutual interference.

A new trend is to transmit a wake-up signal on the same channel as a WLAN signal, for two reasons: (1) A WuR shares part of the RF circuit with a WLAN module to reduce the hardware cost. In addition, a node itself can use its WLAN module to transmit a wake-up message to activate other nodes, without requiring an extra transmitter. (2) A WuR is used for carrier sense and link quality detection, etc., besides the wake-up control. The wake-up control can be implemented by two methods: (i) Frame length of WLAN signals is adjusted to transmit a wake-up message from a WLAN module to a WuR (Chebrolu and Dhekne 2009; Tang et al. 2015). (ii) WLAN-emulated OOK is used to transmit a wake-up message by switching on/off inside a WLAN signal. In either case, a WuR performs envelope detection to receive a wake-up message, and the latter is more spectrum efficient.

Co-existence of Wake-Up Signals and WLAN Signals

When transmitting a wake-up signal on the same channel for WLAN signals, there is a problem of co-existence. In WLANs, continuous space

longer than DIFS (DCF inter-frame space) is usually regarded as an idle channel. To avoid a long idle period in an OOK-modulated signal, some mechanism, like Manchester coding, is applied (Tang et al. 2012). In addition, to further avoid interference, in the WLAN-emulated OOK, OOK is applied to the payload of a WLAN signal, but its header is kept unchanged, telling adjacent nodes when the wake-up signal ends (Park et al. 2016).

Unicast Wake-Up Versus Group Wake-Up

Wake-up control is usually used for the downlink traffic, where an AP activates a node when a packet is ready for the node. Using a unique wake-up ID helps to avoid false wake-up in this case. There is also broadcast traffic in a WLAN, but activating each node successively leads to much overhead. Therefore, a group wake-up is also necessary, where all nodes belonging to a group wake up together to receive a message from the AP.

Sometimes a selective wake-up among a group of nodes is also necessary. An AP without knowing the channel state information may try to activate a node whose link happens to be in the deep fading. A solution is to reuse a WuR for monitoring the channel. The AP sends a group wake-up ID. WuR of each node in the group monitors this wake-up message and, if its channel quality (SNR, signal-to-noise ratio) is above a threshold, contends to initiate its own reception (Tang and Obana 2017). This helps to improve the transmission rate and spectrum efficiency.

Wake-Up Latency

Due to the hardware constraint, a WLAN module, when receiving a wake-up request, cannot wake up immediately and has to transit from Power-off to the fully functional, active state. This transition period is called wake-up period and its length is the wake-up latency (Tang and Obana 2018). In the wake-up period, most time is for the high-frequency clock to get stable. This wake-up latency will cause a problem because the channel remains idle when it is expected to be busy, and some other node may interrupt with a new transmission, and the node in the wake-up transition will wake up to find the channel is already busy, which leads to a false-wake-up. In the unicast wake-up, this can be solved by letting the sender transmit a long preamble to hold the channel or transmit a control frame to reserve the channel.

The idleness per node has different patterns. In the case of long-term idleness, turning on a WLAN module from Power-off to the active state only has an initial delay. A loose integration of a WuR and a WLAN module works relatively well. On the other hand, to aggressively turn off WLAN modules in the short-term idleness (e.g., when other nodes are occupying the channel), a tight integration of a WuR and a WLAN module is necessary to reduce the impact of wake-up latency, which also requires a tight cooperation between a WLAN module and its associated AP.

Sensitivity

To reduce power consumption, a WuR uses a simple circuit of envelope detection without large power amplification. This affects the sensitivity of a WuR and the wake-up range. Fortunately, in the indoor environments with dense deployment of APs, the effective coverage of each AP is usually several meters, and the sensitivity problem of a WuR is not very serious.

Key Applications

The main application of radio-on-demand WLAN is in reducing the power consumption of mobile devices and future IoT devices that use the IEEE 802.11 series protocols.

Introduction

In cellular networks, a great number of users rely on a single centralized base station (BS) to communicate. Yet, base stations do not always

know when users may request access to the network, and they need to find ways to serve these unexpected users. This problem is addressed by a whole field of research, namely, random access (RA). There are multiple scenarios where RA can be used, e.g., first connection to the network, uplink (UL) scheduling request, timing alignment (TA) for non-synchronized users, positioning, etc. The most important scenario however, for which there exists no other method in wireless networks, is when the user is not known to the BS. On first connection, the BS does not expect the specific new user and has no other choice but to allocate specific resources that any user can use to make its presence known.

An inevitable consequence is that when multiple users compete for the same resource at the same time, the transmissions collide and cannot be decoded by the BS. Indeed, collisions can never be fully avoided, and RA techniques aim at reducing their probability while achieving an efficient trade-off between collision probability and resource usage. With the rise of the Internet of things (IoT), which relies on massive machine-type communication (MTC), random access protocols have seen a renewed interest in the recent years (Laya et al. 2014; Ijaz et al. 2016; Ferdouse et al. 2017) to cope with unprecedentedly high user density.

In this entry, an overview of the fundamental principles of random access and contention resolution is carried out in section “[Fundamentals of Random Access](#)”; how the main cellular communication systems implement these methods is studied in section “[Random Access in Practical Systems](#).” Finally, an outlook on the future of random access is discussed in section “[Future Outlook of Random Access](#).”

Fundamentals of Random Access

In this section, the two main families of random access are introduced. Methods for mitigating network congestion are then presented.

Radio Access Protocols

There exist two main categories of radio access: contention-based and reservation-based, both using random access to a certain amount.

Contention-Based

The first wireless RA system, ALOHAnet, was developed in the early 1970s by Norman Abramson's team of the University of Hawaii, using a **pure Aloha** protocol. Users would send their message at a random time on an uplink channel, and the base station would later broadcast messages it received so the users could know if their message collided with someone else's. Collision may appear when two or more transmissions appear at the same time. These transmissions may partly or fully interfere each other when they are initiated within each other vulnerable time. The vulnerable time can last for an overall of two transmission slots. Roberts proposed in 1972 (and later published in 1975) an improved version, namely **slotted Aloha** (Robert 1975), where RA slots were defined to limit the time that a transmission can be initiated. This proposal reduces the vulnerable time to one slot.

When a collision occurs, messages are assumed to be lost. This leads to high delay and low energy and spectral efficiency, as devices have to make multiple RA attempts. Ultimately, this can lead to network congestion.

Reservation-Based

For high traffic and long messages, contention-based RA is not a viable solution. To resolve this issue, modern wireless communication networks adopted a reservation-based RA, where each user gets assigned to a specific resource. As shown in Fig. 1, reservation-based protocols enable full utilization of the channel.

This can be achieved by using an additional handshake step, e.g., a preamble handshake. The principle of this method is to allocate a small portion of the spectrum to a contention-based step where users send a preamble. Preambles are very short messages mainly intended to make the user's presence known to the BS. The BS will then broadcast a RA response (RAR) to set up a dedicated connection with the user. There can be

multiple orthogonal preambles, meaning that the BS will detect multiple users who have randomly chosen different preambles.

This is particularly efficient for large messages and high traffic, preambles are indeed much smaller than messages, and the network can over-provision their number to reduce collision probability at this step. Collisions only lead to RA retry, which is more efficient than sending a whole message again.

A detailed example of a reservation-based RA system is presented in section "[RA in 4G LTE/LTE-Advanced](#)" with the Long-Term Evolution (LTE) RA procedure.

Collision Avoidance and Resolution

To address the collision issue and maximize throughput, techniques have been developed to take advantage of additional information.

Channel Sensing

In Aloha, users are unaware of their surrounding, and channel utilization cannot exceed $1/e$. To address this issue, Kleinrock and Tobagi (1975) proposed the **carrier-sense multiple access (CSMA)** protocol, which is contention-based and non-slotted. Its principle is that, before transmitting, a user senses if the channel is busy. In its purest form, namely, **1-persistent CSMA**, the user will not send its message as long as the channel is busy but will send it as soon as it detects that the channel is idle. In case two users were waiting for the current user to end, its transmission collides. An improvement of this technique is **p-persistent CSMA**, where users transmit with probability p as soon as they detect the channel is idle. Another variation is **nonpersistent CSMA**, where users stop sensing the channel if it is busy and wait a random amount of time before sensing it again. Channel throughput performance of these schemes is shown in Fig. 1.

This method can be adapted to slotted transmissions where messages are sent on multiple consecutive slots, during which the channel can be sensed as busy. This method performs best when the round-trip delay (RTD) between the users and the BS is negligible. Large cellular

Random Access Technology in Cellular Networks, Fig. 1 Random Access protocols Throughput (Kleinrock and Tobagi 1975)

networks, where RTD can reach orders a magnitude of 1 ms, cannot use this method. Therefore, protocols based on CSMA are only used in local networks such as Wi-Fi (IEEE Computer Society 2016).

Randomized Access Control

Reservation-based systems however use slotted Aloha to send preambles and cannot sense the channel. To prevent users from colliding over and over again as they all attempt RA on the next slot, users have to temporarily refrain from accessing the network. This can be achieved by using a **backoff** or a **barring** mechanism.

In the **random backoff** scheme, users wait for a random period of time after a collision before attempting RA again. In another variation, the **binary exponential backoff**, each time a user collides, it doubles the maximum random amount of time it can wait, thus doubling the expected amount of waiting time.

The **barring** scheme, on the other hand, adds another step before attempting RA again. Users have to randomly draw a number between 0 and 1 and compare it to the **persistence probability p**. If it is greater than p, they are allowed to attempt RA. Although both schemes look similar, barring distinguishes itself by allowing the barring parameter p to be modified and to be different for

different categories of users, as detailed in section “[RA for massive MTC](#).”

These two schemes are similar because they temporarily alleviate the load by preventing users from trying to access the network. Essentially, they both seek to optimally spread the traffic in time. These schemes are pushed to their limits with the **dynamic backoff** from Lin et al. (2016), while Rivero-Angeles et al. (2001) proposed the ancestor of **dynamic access class barring**. These schemes are essentially search algorithms that estimate the number of users to determine the optimized backoff window or barring parameter.

Collision-Free

To enable collision-free access, the users must be scheduled before they attempt to access the network. This can be achieved by using paging, where the BS calls out specific users. If they are listening, they may initiate a collision-free connection. For this scheme to be efficient however, the BS needs to make accurate guesses as to who is listening and needs resources.

Assuming perfectly random traffic, the BS cannot make any accurate guess, so users have to be very few and/or constantly scanning for a resource grant; otherwise a lot of downlink control resource is wasted. As a result, this method is either suited for very small networks (it is used in Bluetooth (Bluetooth Special Interest Group

2016)), delay-tolerant applications (users have to wait to be called to transmit uplink messages), and/or users with little to no energy constraints.

However, persistent scheduling (see section “[New techniques for Random Access](#)”) aims at using learning techniques to predict incoming traffic and allow collision-free access to a certain extent.

Random Access in Practical Systems

The history of RA follows that of multiple access: each generation of networks brings a radically different technology, and some of them can wait decades before being used. In this section, implementations of such technologies in standards are presented. Latest techniques for massive MTC are discussed.

RA in 1G Systems

Before cellular systems, the main radio access method was **push-to-talk**, so the RA was a pure Aloha protocol on a given channel. The first-generation (1G) system, Advanced Mobile Phone System (Tanenbaum and Wetherall 2011), brought access and control channels. Outgoing calls were done by (digitally) sending one’s and the receiver’s identifiers on a **pure Aloha** uplink control channel. The rest of the time, the devices were constantly listening to the downlink paging channel.

RA in 2G Systems

In the second-generation Global System for Mobile communications (GSM), a **slotted Aloha** reservation-based system was introduced. The GSM RA channel (ETSI 1996) is used to transmit a small message that contains the user’s identifier and can be used to request an uplink grant for a short message service, for instance. There is only one slot available, so if two or more users attempt RA at the same time, the BS will not be able to decode the resulting collided transmission and will not provide a RAR. Users then use **random backoff**. The BS also defines a maximum number of RA attempts.

RA in 3G Systems

The third generation of cellular networks Universal Mobile Telecommunications System (3GPP 2017a) uses a slotted Aloha reservation-based RA system. Preambles are coded with a sequence of 256 repetitions of Hadamard codes of length 16, thus making **16 orthogonal preambles**.

The user randomly chooses a signature from the set of available signatures within its Access Service Class, similar to **ACB** (see section “[RA for massive MTC](#)”), and sends it on the physical RA channel (PRACH). The BS responds on the Acquisition Indicator Channel by repeating the preamble and adding an acknowledgment (ACK).

If the ACK is negative, the user performs **random backoff** with a predetermined time interval. If no ACK is received at the user equipment’s (UE) side, since the signature is not detected at base station, the user attempts RA again and ramps up in transmit power. Finally, if the ACK is positive, the user sends a RACH message (that includes user-specific connection setup information) in a dedicated slot matching the preamble signature. If two or more users sent the same preamble, the RACH messages will collide and will not be acknowledged. Collided users then proceed to random backoff.

RA in 4G LTE/LTE-Advanced

With the growing number of connected devices and the stringent synchronization requirements of the new multiplexing’s scheme, namely, orthogonal frequency-division multiplexing, RA fulfilled both the role of regular network access and also that of uplink synchronization, thanks to its preamble sequence’s properties.

LTE’s RA is a reservation-based system that uses **64 preambles**, 10 of which are reserved for contention-free RA (3GPP 2011), in a dedicated slotted Aloha control channel. These preambles are generated using a Zadoff-Chu sequence (Wen et al. 2006). Chu (1963, 1972) introduced these complex-polyphase sequences that have perfect autocorrelation properties, making them orthogonal by operating a cyclic shift.

LTE’s RA is a four-step procedure (see Fig. 2) with the following steps (3GPP 2016):

Random Access Technology in Cellular Networks, Fig. 2 RA procedure in LTE (3GPP 2017b)

- Step 1: The user equipment (UE) chooses a random preamble from the 54 orthogonal preambles and transmits it on the physical random access channel (PRACH).
- Step 2: The BS, named evolved node B (eNB), sends a random access response on the physical downlink shared channel that includes a TA command, a temporary cell radio network temporary identifier (C-RNTI), and an uplink grant on the physical uplink shared channel (PUSCH).
- Step 3: The UE transmits its identity using the C-RNTI to initiate a connection on the PUSCH.
- Step 4: If there was no collision in step 1, the eNB transmits a contention resolution message acknowledging the UE. Otherwise, UEs that collided attempt RA again.

Collisions happen at step 1. Users that collide will go through steps 2 and 3, and contention resolution cannot take place before step 4, resulting in additional delay and energy consumption for the UEs that collide. Note that steps 3 and 4 are not used in contention-free RA, e.g., for cell handover when the UE is already known by the network. Instead, it consists of three steps as the eNB assigns a preamble before step 1.

In case of a collision, users proceed to **binary exponential backoff**.

RA for Massive MTC

To prevent machine-to-machine (M2M) traffic from adversely affecting human-to-human (H2H) communication, **access class barring** (ACB) (3GPP 2012) is a standardized approach in LTE/LTE-Advanced. It assigns different persistence levels (the p probability, see section “Randomized Access Control”) to different traffic classes in order to ensure that high-priority users do not suffer from congestion caused by low-priority ones. **Dynamic RACH allocation** (3GPP 2011) is another technique proposed to alleviate the high RACH load problem in LTE, which is based on allocating additional RACH resources according to current traffic load conditions. Finally, **extended access barring** is the extreme case where certain users are completely barred from accessing the network ($p = 0$) as long as the BS judges that RACH congestion is too high.

LTE Release 13 introduced new features specifically aimed at enabling massive MTC (GSMA 2016): extended coverage GSM IoT (EC-GSM-IoT), enhanced MTC (eMTC),

and narrowband IoT (NB-IoT). The main focus however is to offer increased range and battery. eMTC improves on LTE with additional features such as extended idle-mode discontinuous reception and semi-persistent scheduling. These techniques enable the BS to learn traffic MTC devices' traffic patterns, thus improving **load prediction**. NB-IoT is essentially a simplified narrower-band LTE and comes with a new PRACH, the narrowband PRACH; this essentially means that RA is dedicated to MTC devices, contrarily to ACB that restricts their access to the PRACH.

Future Outlook of Random Access

Although it is critical to ever-growing multiple access networks, RA in standards has known little to no major evolution since slotted Aloha was introduced in the 1970s. Efforts were made to prevent congestion and maintain slotted Aloha's performances, but that is as far as current systems go. However, with the IoT becoming a reality, this should change rapidly. In this section, recent technologies are presented, and the future of RA is discussed.

New Requirements for 5G and the IoT

The massive MTC scenario represents a paradigm switch from traditional wireless networks. It relies on an unprecedented number (Osseiran et al. 2014) of low-energy consumption devices that are expected to be inactive most of the time (Qi et al. 2015), may be far from the BS, and sporadically transmit small messages with bursts of traffic peaks (3GPP 2011).

While, in LTE, UL requests are usually handled by the physical uplink control channel (PUCCH) for already connected UEs, they can only be made through RA for MTC devices waking up. This, along with the number of users, M2M traffic will undoubtedly overload the RACH. And while LTE was designed with enough overprovisioning to achieve a 99% RA success probability, it is commonly accepted that

a higher collision probability is expected for the IoT scenario (Lo et al. 2011).

Although spectacular predictions in the early 2010s of a trillion devices by 2020 have since deflated (Nordrum 2016), around 30 billion devices are expected to be connected by 2020 and 75 billion by 2025 (see Fig. 3). It must be noted that the H2H market has already reached maturity in most part of the world and that most of the additional devices are expected to be MTC devices, while they are a minority today.

Another challenge to future RA systems is the burstiness of the traffic. Event-driven communication may lead to high traffic bursts that can pose a big threat to network access. A traffic burst can be modeled by a beta distribution (3GPP 2011) where the traffic peak is temporarily much higher than the average expected traffic. This has been shown to lead to congestion in traditional LTE networks.

New Techniques for Random Access

Many groundbreaking RA techniques have been proposed in the recent years and are good candidates to be part of future cellular systems. Some of the most promising methods are:

- **Coded RA:** Some new techniques focus on improving slotted Aloha's spectral efficiency. Wunder et al. (2015) proposed to use sets of preambles as a code, effectively increasing the overall spectral efficiency and theoretically achieving 100% spectrum usage.
- **Virtual preambles RA:** Techniques to virtually increase the number of preambles have been proposed. For instance, Munir et al. (2014) propose to send multiple RAR (with different UL grants) to any received preamble. If users collide at step 1 of the LTE procedure, they still have a chance to be served at step 3.
- **Non-orthogonal RA:** A revolutionizing approach is to design a pure contention-based RA, as opposed to reservation-based, where collisions can be resolved. Shirvanimoghaddam et al. (2017) propose such a scheme, which uses successive interference

Random Access Technology in Cellular Networks, Fig. 3 Number of connected devices in billions by 2025 (Nordrum 2016)

cancellation to resolve collisions and shows promising results for moderate traffic loads.

- Semi-persistent scheduling: MTC devices are expected to have a sporadic traffic load and be in sleep mode most of the time. Such traffic can be memorized by the BS. Qi et al. (2015) propose a semi-persistent paging mechanism by predicting when the MTC devices will be awake. This can reduce the RA load by allowing some collision-free access.
- Learning-based RA: Although it is assumed that traffic is purely random, users in a given cell will not always change. This is especially true for MTC devices that will mostly be stationary (e.g., sensors). Thus, it is possible for users to learn to share RA resources more efficiently. Bello et al. (2016) used Q-learning to achieve 100% RACH throughput by having users to converge to dedicated RACH slots.

Conclusion

RA in current cellular networks relies on well-established technologies that have proven to be

sufficient for H2H communication. However, the IoT will change the game in the upcoming years: there will be more devices, these devices will be more heavily dependent on RA, and they will access the network in bursts of traffic.

Random access, by definition, works under the assumption that the network is not able to predict when devices will need to access the network. However this does not need to always be the case. Nowadays, machine learning, traffic prediction, and context-aware mechanisms are gaining more and more traction. Indeed, one can argue that a certain amount of the upcoming massive MTC traffic, if not a significant amount, can be predicted and served by using alternative methods.

The next stepping stone of random access will be to only be used for communications that are truly random.

Problem Definition

As a significant complementary tool to the Poisson point process and binomial point process models in stochastic geometry, probabilistic distance-based models have been extensively studied and applied for interference analysis in finite wireless networks (Tong and Pan 2017; Tong et al. 2017a). Such models eventually involve distributions of the distances between transmitting and receiving nodes, called nodal distance distributions (NDDs) in this entry. NDDs intrinsically depend on network coverage and nodal spatial distribution. Depending on whether one of the nodes is given or not, there are two types of NDDs. One is Ref2Ran NDD from a given reference node to a random node and the other is Ran2Ran NDD between two random nodes. Both of them have been widely utilized for interference analysis in wireless networks, as shown in Ahmadi et al. (2013, 2015), Tong et al. (2017b), Tong and Pan (2017), and the references therein. How to effectively obtain the relevant NDDs is therefore significant to interference modeling and analysis in wireless networks. We have surveyed the state-of-the-art approaches in Tong et al. (2017a), as also briefly shown and extended below.

Key Results

Ref2Ran NDD

A systematic recursive approach has been proposed in Ahmadi and Pan (2014) to obtain the Ref2Ran NDD from an arbitrary reference node to a random node inside an arbitrary polygon. Firstly, the Ref2Ran NDD from a vertex of an arbitrary triangle to a random node inside the triangle is obtained by using the area-ratio approach, based on which the Ref2Ran NDD from an exterior or interior reference node to a random node inside the triangle is then obtained by using a decomposition and recursion (D&R) method. In this entry, an NDD from an arbitrary reference node to a random node inside an arbitrary triangle is the so-called Ref2Ran triangle-NDD.

Since any polygon can be triangulated, the Ref2Ran NDDs associated with an arbitrary polygon can be obtained based on the obtained Ref2Ran triangle-NDDs. Specifically, if the reference node R is inside the polygon, the polygon can be triangulated from R as shown in Fig. 1a; otherwise, if R is outside, the triangle can be triangulated from a vertex as shown in Fig. 1b. Let N denote the number of generated triangles after the triangulation ($N = 6$ and 4 for the polygons shown in Fig. 1a, b, respectively), S_i^Δ the area of triangle $\mathcal{T}_i$, S the area of the polygon, and $F_i^\Delta(d)$ the cumulative distribution function (CDF) of the distance from R to a random node inside the triangle $\mathcal{T}_i$ (which has already been obtained). Then, with a weighted probabilistic sum, the CDF of the distance from R to a random node inside the polygon is

$$F(d) = \sum_{i=1}^N \frac{S_i^\Delta}{S} F_i^\Delta(d). \quad (1)$$

It is possible that different subareas of a network have different node densities (the so-called tiered network). For this case, the above weighted probabilistic sum approach in (1) is still applicable but with different weights due to the node density difference. Take the network shown in Fig. 1c, for example, and suppose the node density ratio between $\mathcal{P}_1$ (the white area) and $\mathcal{P}_2$ (the grey area) is $\lambda_1 : \lambda_2$ (λ_1 and λ_2 are not zero simultaneously). Let S_i denote the area of $\mathcal{P}_i$ and $F_i(d)$ the CDF of the distance from R to a random node inside $\mathcal{P}_i$ (which has been obtained in (1)). Then the CDF of the distance from an arbitrary reference node R to a random node inside the whole area $\mathcal{P}_3$ ($\mathcal{P}_1$ plus $\mathcal{P}_2$) is

$$F_3(d) = \sum_{i=1}^2 \frac{S_i \lambda_i}{\sum_j S_j \lambda_j} F_i(d). \quad (2)$$

Ran2Ran NDD

For Ran2Ran NDDs, we recently proposed an approach in Tong and Pan (2017), which can handle the networks in the shape of arbitrary polygons as well as the polygons with different

Random Distance Distribution, Fig. 1 An arbitrary reference node R and arbitrary polygons (Tong et al. 2017a). (a) R is inside. (b) R is outside. (c) Tiered structure. (d) Tiered structure with triangulations

node densities in different subareas. The D&R method is also utilized to this end through polygon triangulation. Specifically, Ran2Ran NDDs associated with arbitrary triangles (the so-called Ran2Ran triangle-NDDs) are firstly obtained, which include the Ran2Ran NDD within an arbitrary triangle and that between two arbitrary triangles. Then Ran2Ran NDDs associated with arbitrary polygons can be obtained through the D&R method. We refer interested readers to Tong and Pan (2017) for more details.

Nonuniform node distribution is also considered in the above approach. Take the irregular polygon with a triangulation as shown in Fig. 1b, for example. Assume the node density ratio among $\mathcal{T}_1$, $\mathcal{T}_2$, $\mathcal{T}_3$, and $\mathcal{T}_4$ is $\lambda_1 : \lambda_2 : \lambda_3 : \lambda_4$ ($\lambda_1, \lambda_2, \lambda_3$, and λ_4 are not zero simultaneously). Through D&R, the CDF of the Ran2Ran NDD within the polygon is given by a weighted probabilistic sum,

$$F(d) = \sum_{i=1}^4 \sum_{j=1}^4 \frac{S_i^{\Delta} \lambda_i S_j^{\Delta} \lambda_j}{\left(\sum_{k=1}^4 S_k^{\Delta} \lambda_k \right)^2} F_{ij}^{\Delta}(d), \quad (3)$$

where S_x^{Δ} is the area of triangle $\mathcal{T}_x$, and $F_{ij}^{\Delta}(d)$ is the CDF of the Ran2Ran NDD within triangle $\mathcal{T}_i$ if $i = j$, or between two triangles $\mathcal{T}_i$ and $\mathcal{T}_j$ if $i \neq j$, which have been obtained above as the Ran2Ran triangle-NDDs.

For tiered polygons shown as in Fig. 1c, the CDFs of the Ran2Ran NDDs within $\mathcal{P}_1$ and $\mathcal{P}_2$, i.e., $F_{11}(d)$ and $F_{22}(d)$, respectively, can be obtained by (3). Assume the node density ratio among $\mathcal{P}_1$ and $\mathcal{P}_2$ is $\lambda_1 : \lambda_2$ (λ_1 and λ_2 are not zero simultaneously). To obtain the CDF of the Ran2Ran NDD between $\mathcal{P}_1$ and $\mathcal{P}_2$, i.e., $F_{12}(d)$, we first triangulate each of them as shown in Fig. 1d and get 3 and 11 triangles, respectively. Then with a weighted probabilistic sum,

$$F_{12}(d) = \sum_{m=1}^3 \sum_{n=1}^{11} \frac{S_m^{\Delta_1} S_n^{\Delta_2}}{\sum_{i=1}^3 S_i^{\Delta_1} \sum_{j=1}^{11} S_j^{\Delta_2}} F_{mn}^{\Delta}(d), \quad (4)$$

where $S_x^{\Delta_y}$ is the area of the x -th triangle in $\mathcal{P}_y$ and $F_{mn}^{\Delta}(d)$ is the CDF of the Ran2Ran NDD between the m -th triangle in $\mathcal{P}_1$ and the n -th triangle in $\mathcal{P}_2$. With $F_{11}(d)$, $F_{22}(d)$, and $F_{12}(d)$ obtained above, $F_{33}(d)$, $F_{13}(d)$, and $F_{23}(d)$ can be obtained by

$$F_{33}(d) = \sum_{i=1}^2 \sum_{j=1}^2 \frac{S_i \lambda_i S_j \lambda_j}{\left(\sum_{k=1}^2 S_k \lambda_k\right)^2} F_{ij}(d), \quad (5)$$

$$F_{3i}(d) = \sum_{j=1}^2 \frac{S_j \lambda_j}{\sum_{k=1}^2 S_k \lambda_k} F_{ij}(d), \quad (i \in \{1, 2\})$$

where S_x is the area of $\mathcal{P}_x$, and $F_{ij}(d)$ is the CDF of the Ran2Ran NDD within $\mathcal{P}_i$ if $i = j$, or between $\mathcal{P}_i$ and $\mathcal{P}_j$ if $i \neq j$.

Interference Analysis

Assume a general path loss model. The path loss ratio of the transmission power at distance d is

$$L(d) = \beta d_0^\alpha d^{-\alpha}, \quad (6)$$

where β is a path loss constant determined by the hardware features of transceivers, d_0 is a given reference distance, and α is the path loss exponent. As a result, the received signal strength at distance d is

$$P_r(d) = L(d)P_t, \quad (7)$$

where P_t is the transmission power. Therefore, given a distance distribution, the distributions of path loss ratio and received signal strength can also be obtained by using the change-of-variable technique. For all the transmitters in the network, assume that the i -th transmitter has a transmission power of P_i . The cumulative interference at the receiver from all its interfering nodes is

$$I = \sum_i P_i L(d_i), \quad (8)$$

where $L(d_i)$ is given in (6) and d_i is the distance from the receiver to the i -th interfering node. Correspondingly, the distribution of the interference at the receiver can also be obtained based on distance distributions.

Key Applications

The interference model introduced above can be utilized to analyze the distributions of some important performance metrics in wireless networks, such as signal-to-interference-plus-noise ratio (SINR), link capacity, etc. As shown in (8), the key is to obtain the distributions of the relevant distances. Some examples are introduced below.

In Zhuang et al. (2011), the NDDs from a BS (reference node) to an arbitrary cellular user (random node) in the same hexagonal cell or to the users in its adjacent cells were derived. Based on the obtained NDDs, the received exterior co-channel interference at a BS from a transmitting cellular user of any six adjacent cells was explicitly analyzed. In Ahmadi et al. (2013), the obtained NDDs were further utilized to analyze the cumulative exterior interference at a BS from its all first-layer neighbor cells. In Ahmadi et al. (2015), the distance distributions associated with arbitrarily shaped cells in tiered cellular systems were utilized to model and analyze a cellular network consisting of a single macrocell and multiple randomly deployed femtocells in a link reusing scenario. The distributions of interference were derived, based on which the system outage probability was obtained. In Tong et al. (2017b), we proposed a framework using the probabilistic distance model introduced above to obtain the distributions of the signal and interference strengths, and further SINR, based on which, the performance metrics that are functions of the SINR could be analyzed, such as outage probability and capacity.

Definitions

In a practical biological system, chemical reactions widely occur during the molecule propagation environments; thus it is very important to understand the channel response of the molecular communication system under various reaction-diffusion channels. Historically, chemical reactions describe the changes only involved in the positions of electrons in the forming and breaking of chemical bonds between atoms, with no change to the nuclei. There are basically four types of reactions categorized in terms of their functionalities, namely, synthesis reactions, decomposition reactions, oxidation and reduction reactions, and complexation reactions. This chapter focuses on the mathematical models and simulation approaches for the reaction-diffusion channels under the first-order reaction, second-order reaction, and enzyme reaction.

Mathematical Models for Reaction-Diffusion Channel

The simplest propagation method in molecular communication is free diffusion, where the

molecules' random motion is governed by the Brownian motion (Berg 1993). In a practical biological system (e.g., human body), numerous complex chemical reactions take place in the human body. The general reaction-diffusion equation for species S is Debnath (2005, Eq. (8.12.1))

$$\frac{\partial C_S}{\partial t} = D_S \nabla^2 C_S + f(C_S, \vec{r}, t), \quad (1)$$

where $f(\cdot)$ is the reaction term.

First-Order Reaction

With the emission of A information molecules at the transmitter, the fundamental mechanism of the first-order reaction can be described as

and k_F is the forward reaction rate constant with units in $\text{molecule}^{-1}\text{m}^3\text{s}^{-1}$.

The general reaction-diffusion equation for the first-order reaction is written as

$$\begin{aligned} \frac{\partial C_A}{\partial t} &= D_A \nabla^2 C_A - k_F C_A, \\ \text{and } \frac{\partial C_B}{\partial t} &= D_B \nabla^2 C_B + k_F C_A, \end{aligned} \quad (3)$$

where D_A and D_B are the constant diffusion coefficients of the A and B molecules and C_A and C_B are the time-varying concentrations of the A and B molecules, which can be solved using (3) with the defined initial and boundary conditions. The channel responses of molecular communication system with the first-order reaction have been studied in Chou (2015), Heren et al. (2015), Ahmadzadeh et al. (2016), and Deng et al. (2017a). The first-order reaction examples include

and

Second-Order Reaction

With the emission of A information molecules at the transmitter, the fundamental mechanism of the second-order reaction can be described as

and k_B is the backward reaction rate constant with units in s^{-1} .

The general reaction-diffusion equation for the second-order reaction is written as

$$\begin{aligned} \frac{\partial C_A}{\partial t} &= D_A \nabla^2 C_A - k_F C_A C_B + k_B C_C, \\ \frac{\partial C_B}{\partial t} &= D_B \nabla^2 C_B - k_F C_A C_B + k_B C_C, \\ \text{and } \frac{\partial C_C}{\partial t} &= D_C \nabla^2 C_C - k_B C_C + k_F C_A C_B, \end{aligned} \quad (7)$$

where D_C is the constant diffusion coefficient of the C molecules and C_A , C_B , and C_C are the time-varying concentrations of the A , B , and C molecules, which can be solved using (7) with the defined initial and boundary conditions. The tractable analytical solutions for the second-order reaction are usually not easy to obtain, and the channel responses of molecular communication system with the second-order reaction have been studied in Chou (2015), Ahmadzadeh et al. (2016), and Deng et al. (2017b). The first-order reaction examples include

and

Enzyme Reaction

In a practical biological system, the biological catalysts (i.e., enzymes) take part in various chemical reactions. Motivated by this, the enzymatic reactions in the propagation environments were studied in Noel et al. (2014) for intersymbol interference (ISI) reduction. With the emission of A information molecules at the transmitter, the

fundamental mechanism of enzymatic reactions can be described via Michaelis-Menten kinetics as

where E is the enzyme molecule, EA is the intermediate, A_P is the degraded A molecule, and k_1 , k_{-1} , and k_2 are the reaction rate constants with units in molecule⁻¹m³s⁻¹, s⁻¹, and s⁻¹.

To evaluate the channel response of the molecular communication system, we describe the spatiotemporal behavior of the information, enzyme, and intermediate molecules via reaction-diffusion partial differential equations as

$$\begin{aligned} \frac{\partial C_A}{\partial t} &= D_A \nabla^2 C_A - k_1 C_A C_E + k_{-1} C_{EA}, \\ \frac{\partial C_E}{\partial t} &= D_E \nabla^2 C_E - k_1 C_A C_E + k_{-1} C_{EA} \\ &\quad + k_2 C_{EA}, \\ \frac{\partial C_{EA}}{\partial t} &= D_A \nabla^2 C_{EA} + k_1 C_A C_E - k_{-1} C_{EA} \\ &\quad - k_2 C_{EA}. \end{aligned} \quad (11)$$

Solving (11) along with the initial and boundary conditions defined at the emission and the reception of the molecular communication system, the time-varying concentration of each type of molecules can be obtained. Note that solving (11) in a closed form is analytically intractable (or at least very difficult) for the boundary conditions that are commonly considered in MC (point source, preexisting enzyme, etc.).

Simulation Approaches for Reaction-Diffusion Channel

The particle-based simulations can be generally categorized as the mesoscopic and microscopic models (Noel et al. 2017). In mesoscopic model, the spaces are divided into many subvolumes (i.e., cubes), where the number of molecules in each subvolume is individually counted (Chou 2015). In microscopic model, molecules are tracked individually in each simulation step

(Deng et al. 2016; Ahmadzadeh et al. 2016). Here, we limit ourselves to the microscopic simulation model due to its simplicity, efficiency, and generality.

Diffusion

The time is divided into small simulation intervals of size Δt , and each time instant is $t_m = m\Delta t$, where m is the current simulation index. According to Brownian motion, the displacement of a molecule in each dimension in one simulation step Δt can be modeled by an independent Gaussian distribution with variance $2D\Delta t$ and zero mean $\mathcal{N}(0, 2D\Delta t)$. The displacement ΔS of a molecule in a 3D fluid environment in one simulation step Δt is therefore

$$\Delta S = \{\mathcal{N}(0, 2D\Delta t), \mathcal{N}(0, 2D\Delta t), \mathcal{N}(0, 2D\Delta t)\}. \quad (12)$$

In each simulation step, the number of molecules and their locations are stored. Note that the accuracy of the simulation results depends on the size of simulation step Δt .

First-Order Reaction

The first-order reaction in the microscopic regime can usually be simulated using the probability (Andrews 2009, Eq. (22))

$$P_f = 1 - e^{-k_F \Delta t}, \quad (13)$$

where Δt is the simulation step.

Second-Order Reaction

With two reactants A and B , we need to carefully determine the binding radius r_{AB} . When A and B are physically separated and the binding radius r_{AB} is much larger than the expected separation of the A and B molecules due to diffusion in the next simulation time step, the binding will occur in the next time step. Note that the root-mean-square of the separation of the A and B molecules in a single simulation time step is Andrews and Bray (2004, Eq. (23))

$$r_{\text{rms}} = \sqrt{2(D_A + D_B)\Delta t}. \quad (14)$$

If Δt is sufficiently large, then $r_{\text{rms}} \gg r_{AB}$, and the binding radius r_{AB} can be defined as Andrews and Bray (2004, Eq. (27))

$$r_{AB} = \left(\frac{3k_F \Delta t}{4\pi} \right)^{\frac{1}{3}}. \quad (15)$$

When $r_{\text{rms}} \gg r_B$ is not satisfied, the binding radius r_{AB} can be evaluated using numerical methods (Andrews and Bray 2004).

The backward reaction probability can be characterized using

$$P_b = 1 - e^{-k_B \Delta t}. \quad (16)$$

Enzyme Reaction

The enzyme reaction includes the second-order reactions; thus the binding radius of the binding reaction k_1 can be described as

$$r_{EA} = \left(\frac{3k_1 \Delta t}{4\pi} \right)^{\frac{1}{3}}, \quad (17)$$

when $r_{\text{rms}} \gg r_{EA}$, otherwise r_{EA} can be obtained using numerical methods (Andrews and Bray 2004).

The probabilities of the unbinding reactions occurring are a function of both the unbinding and degradation rate constants, written as Andrews and Bray (2004, Eq. (14))

$$\Pr(\text{Reaction } k_{-1}) = \frac{k_{-1}}{k_{-1} + k_2} [1 - \exp(-\Delta t (k_{-1} + k_2))], \quad (18)$$

and

$$\Pr(\text{Reaction } k_2) = \frac{k_2}{k_{-1} + k_2} [1 - \exp(-\Delta t (k_{-1} + k_2))], \quad (19)$$

respectively.

Definitions

Receiver mechanisms refer to the set of processes which describe how signaling molecules in the molecular communication environment are sensed by a nanoreceiver.

Historical Background

Molecular communication (MC) is a potentially bio-compatible approach for enabling commu-

nication at micro- to nanoscale. In fact, MC is one of the foremost means of communication between biological entities in nature. The bio-compatibility and abundant use of MC in nature make it an attractive candidate for synthetic MC system design.

Meaningful yet simple models that take the physics of the components of synthetic MC systems (i.e., the transmitter, channel, and receiver) at nanoscale into account are a crucial first step towards synthetic MC system design. In particular, in this entry, a review of the most common receiver models in the MC literature is presented.

In nature, typically, a biological entity such as a cell measures the concentration of signaling molecules in its vicinity via the receptor protein molecules embedded in its surface. These measurements are inherently *stochastic* and corrupted by various noise sources, namely, (1) the random movements of the signaling molecules diffusing from the source to the cell, (2) stochastic degradation and/or production of signaling molecules during diffusion, (3) stochastic binding and unbinding of signaling molecules to the receptor protein molecules on the surface of the cell, and (4) the stochastic nature of the signaling pathways relaying the noisy measurements of the receptors from the exterior to the interior of the cell. Based on the noisy estimation of the concentration of the signaling molecules, the cell decides on a suitable response, see ten Wolde et al. (2016). In the following, noise sources (1), (2), (3), and (4) are referred to as random walk (RW), degradation and production (D&P), receptor kinetic (RK), and signaling pathway (SP) noise sources, respectively.

In the MC literature, different receiver models have been proposed, each taking some of the noise sources mentioned above into account. In particular, in many works, such as Pierobon and Akyildiz (2011a), Mahfuz et al. (2014), a receiver model with only RW noise, the so-called *passive receiver*, is considered. A receiver model considering RW and D&P noise is proposed in Noel et al. (2014). In Pierobon and Akyildiz

Receiver Mechanisms for Synthetic Molecular Communication Systems with Diffusion, Fig. 1 Schematic presentation of three common receiver models: a) passive receiver, b) fully absorbing receiver, and c) reactive receiver

(2011b), ShahMohammadian et al. (2013), RW and RK noise are considered, while the diffusion process and the reaction mechanisms describing RK noise are treated separately. The so-called *fully absorbing receiver* model is proposed in Yilmaz et al. (2014). There, the impact of RW noise and a special case of RK noise are jointly considered. In particular, for RK noise, it is assumed that (I) the surface of the receiver is uniformly covered with infinitely many receptors and (II) the reactions corresponding to RK noise are modeled deterministically, i.e., it is assumed that any collision of a signaling molecule and the receiver surface leads to absorption of the signaling molecule. Extensions of the *fully absorbing receiver* model taking D&P noise into account and relaxing assumption (I) are reported in Heren et al. (2015) and Akkaya et al. (2015), respectively. A receiver model which includes RW and SP noise for two simple approximate signaling pathway models is proposed in (Chou 2015). A receiver model that jointly takes the impact of RW and RK noise with assumption (I) into account is proposed in Deng et al. (2015). A comprehensive model for *reactive receivers* is introduced in Ahmadzadeh et al. (2016), where the joint effects of RW, D&P, and RK noise are considered. This entry reviews the receiver signal models for *passive*, *fully absorbing*, and *reactive* receivers in *diffusive* MC systems, see Fig. 1. Most of the other above-mentioned receiver models are special cases or simple extensions of these three models.

Key Applications

These receiver models can be applied for the design and optimization of synthetic MC systems, from modulation schemes for the transmitter to detection and/or decoding algorithms for the receiver.

Receiver Signal Model

As discussed in the previous section, the received signal is highly random and corrupted by several types of noise. The *random* received signal is denoted by r , its distribution by $f(r)$, and its mean and variance by $\bar{r}$ and σ_r^2 , respectively. The quantitative meaning of r depends on the particular choice of the receiver and will be discussed in detail in the following subsections. Furthermore, this entry focuses on spherical receivers with radius a [m] and the model of r for *one impulsive* release of N identical information (or signaling) A molecules into an unbounded fluid environment at time $t_0 = 0$ by a point transmitter located at a distance d [m] from the center of the receiver. The diffusion coefficient of the A molecules is denoted by D [m²/s]. A summary of the relevant system parameters is provided in Table 1. An example for the typical shape of the mean received signal $\bar{r}$ in diffusive MC systems is depicted in Fig. 2. In particular, when $N = 1$, $\bar{r}$ is referred to as the *channel impulse response* of the considered MC system and denoted by $\bar{h}$, i.e.,

Receiver Mechanisms for Synthetic Molecular Communication Systems with Diffusion, Table 1 Summary of system parameters

Symbol	Definition	Symbol	Definition
a	Receiver radius	D	Diffusion coefficient of A molecules
V	Volume of the receiver hull	k_f	Binding reaction rate constant
d	Distance between transmitter and receiver	k_b	Unbinding reaction rate constant
N	# of impulse release of A molecules	k_d	Degradation reaction rate constant
M	# of receptors on the surface of receiver	r_s	Radius of circular receptor patch

Receiver Mechanisms for Synthetic Molecular Communication Systems with Diffusion, Fig. 2

Example for sample realization and mean of a typical received signal in diffusive MC systems

$\bar{h} = \bar{r}_{|N=1}$. In other words, $\bar{h}$ is in fact the *probability* of receiving one given A molecule. In the following, first, a review of the existing models for $\bar{h}$ is given for the passive, fully absorbing, and reactive receivers. Subsequently, a discussion is provided on the common assumptions adopted in the literature to arrive at mathematically tractable expressions for $\bar{r}$ in the case of $N > 1$. At the end, this entry review some of the existing models proposed for the distribution of r , $f(r)$.

Channel Impulse Response

Passive Receiver

In the passive receiver model, the randomness of r is caused only by the diffusion of the signaling molecules, where the receiver does not influence the propagation of the A molecules. In particular, signaling A molecules in the vicinity of the receiver can enter and leave the receiver via free diffusion, see e.g., Fig. 1a). The passive receiver model is a good approximation for the diffusion of small, uncharged molecules, such as ethanol, urea, and oxygen. These molecules can enter and leave a cell by passive diffusion across the plasma membrane, (Alberts et al. 2009). In the passive receiver model, r is defined as the number of

observed A molecules inside the receiver hull. It has been shown in Noel et al. (2013), Eq. (27) that $\bar{h}$ is given by

$$\bar{h} = \frac{1}{2} \left(\operatorname{erf} \left(\frac{a-d}{\sqrt{4Dt}} \right) + \operatorname{erf} \left(\frac{a+d}{\sqrt{4Dt}} \right) \right) + \frac{\sqrt{Dt}}{a\sqrt{\pi}} \left(\exp \left(-\frac{(a-d)^2}{4Dt} \right) + \exp \left(-\frac{(a+d)^2}{4Dt} \right) \right), \quad (1)$$

where $\operatorname{erf}(\cdot)$ denotes the error function. A common approach, which is referred to as the *uniform concentration assumption*, is to approximate $\bar{h}$ everywhere inside the volume of the receiver, $V = 4/3\pi a^3$, by its value at the center of the receiver. This leads to the following simple expression for $\bar{h}$

$$\bar{h} = \frac{y}{(4\pi Dt)^{3/2}} \exp \left(-\frac{d^2}{4Dt} \right). \quad (2)$$

It was shown in Noel et al. (2013) that (2) provides an accurate approximation for (1) if $a < 0.15 d$ holds.

Fully Absorbing Receiver

For the fully absorbing receiver, the signaling A molecules that reach the receiver via diffusion are absorbed as soon as they hit the receiver surface,

see Fig. 1b). In this case, r is defined as the number of absorbed molecules during infinitesimally small time dt . It is shown in Yilmaz et al. (2014) that the number of absorbed molecule until time t , g , can be obtained as

$$g = \frac{a}{d} \operatorname{erfc}\left(\frac{d-a}{\sqrt{4Dt}}\right), \quad (3)$$

where $\operatorname{erfc}(\cdot)$ denotes the complementary error function. Given (3), $\bar{h}$ can be written as (Yilmaz et al. 2014, Eq. (22))

$$\bar{h} = dg = \frac{a(d-a)}{td\sqrt{4\pi Dt}} \exp\left(-\frac{(d-a)^2}{4Dt}\right) dt. \quad (4)$$

Remark 1 Alternatively, when the receiver counts the number of absorbed molecules during a window of $t_u - t_l$ seconds, $\bar{h}$ can be defined as

$$\begin{aligned} \bar{h} &= g|_{t_u} - g|_{t_l} \\ &= \int_{t_l}^{t_u} \frac{a(d-a)}{\tau d\sqrt{4\pi D\tau}} \exp\left(-\frac{(d-a)^2}{4D\tau}\right) d\tau. \end{aligned} \quad (5)$$

Reactive Receiver

Reactive receiver is a good model for large or polar molecules that cannot passively diffuse through the hull of a cell and have to be detected by external receptors embedded in the surface of the cell. For the reactive receiver model, RW, D&P, and RK noise sources jointly affect r . In particular, the diffusive signaling A molecules can potentially degrade in the channel and those which reach the receiver participate in a reversible bimolecular second-order reaction with receptor protein B molecules on the surface of the receiver to activate receptors and form the ligand-receptor complex C molecules, see e.g., Fig. 1c). The first-order degradation reaction in the channel and the reversible reaction on the receiver surface are given by

and

respectively. Here, k_d , k_f , and k_b denote the degradation reaction rate constant in $[s^{-1}]$, the binding reaction rate constant in $[\text{molecule}^{-1} \cdot \text{m}^3 \cdot \text{s}^{-1}]$, and the unbinding reaction rate constant in $[s^{-1}]$, respectively. For the reactive receiver, r is defined as the number of activated receptors C . The expression describing $\bar{h}$ is derived in (Ahmadzadeh et al. 2016, Eq. (29))

$$\begin{aligned} \bar{h} &= \frac{k_f^* e^{-k_d t}}{4\pi da\sqrt{D}} \left\{ \frac{\alpha W\left(\frac{d-a}{\sqrt{4Dt}}, \alpha\sqrt{t}\right)}{(\gamma - \alpha)(\alpha - \beta)} \right. \\ &\quad + \frac{\beta W\left(\frac{d-a}{\sqrt{4Dt}}, \beta\sqrt{t}\right)}{(\beta - \gamma)(\alpha - \beta)} \\ &\quad \left. + \frac{\gamma W\left(\frac{d-a}{\sqrt{4Dt}}, \gamma\sqrt{t}\right)}{(\beta - \gamma)(\gamma - \alpha)} \right\}, \end{aligned} \quad (8)$$

where $W(n, m) = \exp(2nm + m^2)\operatorname{erfc}(n + m)$, and constants α , β , and γ are the solutions to the following system of equations:

$$\begin{cases} \alpha + \beta + \gamma = \left(1 + \frac{k_f^*}{4\pi aD}\right) \frac{\sqrt{D}}{a}, \\ \alpha\gamma + \beta\gamma + \alpha\beta = k_b - k_d, \\ \alpha\beta\gamma = k_b \frac{\sqrt{D}}{a} - k_d \left(1 + \frac{k_f^*}{4\pi aD}\right) \frac{\sqrt{D}}{a}. \end{cases} \quad (9)$$

Here, k_f^* is defined as

$$k_f^* = \frac{4\pi D a k_f \varphi}{k_f (1 - \varphi) + 4\pi D a}, \quad (10)$$

where φ is a constant that is given by (Ahmadzadeh et al. 2016, Eq. (39))

$$\varphi = \frac{Mr_s^2 (k_f + 4\pi Da)}{a(1 - \lambda)(\pi r_s k_f + 16\pi Da^2) + Mr_s^2 (k_f + 4\pi Da)}, \quad (11)$$

and $\lambda = M \frac{\pi r_s^2}{4\pi a^2}$ is the fraction of the receiver surface covered by M circular receptors, each with radius r_s .

Remark 2 The fully absorbing receiver is a special case of the reactive receiver when $\lambda \rightarrow 1$, $k_b = k_d = 0$, and $k_f \rightarrow \infty$. In this case, reaction equation (7) becomes a pseudo first-order reaction of the form $A \rightarrow C$, with binding reaction rate constant $k_f \rightarrow \infty$, where now C denotes the number of absorbed molecules. However, $k_f \rightarrow \infty$ implies that any collision of a signaling A molecule with the receiver surface leads to the formation of a C molecule, i.e., the reaction is deterministic. It can be shown that under these assumptions (8) simplifies to (3).

Remark 3 The expressions for $\bar{h}$ of the passive and fully absorbing receivers can be extended to take *first-order* degradation reactions in the channel of the form in (6) into account by multiplying the corresponding $\bar{h}$ with $\exp(-k_d t)$. For higher-order enzymatic degradation reactions in the channel, we refer the reader to Noel et al. (2014).

Stochastic Received Signal

In order to calculate the mean and the distribution of r when $N \geq 1$, i.e., $\bar{r}$ and $f(r)$, respectively, the following set of assumptions are commonly made (explicitly or implicitly) in the MC literature. For evaluation of $\bar{r}$, if one assumes that (a) *each* of the RW, D&P, RK, and SP noise sources affects individual A molecules *independently*, i.e., if one assumes that the diffusion, reaction, and reception processes of a given A molecule do not influence the diffusion, reaction, and reception processes of any other A molecule, $\bar{r}$ is obtained as

$$\bar{r} = N\bar{h}. \quad (12)$$

For calculation of $f(r)$, in addition to assumption (a), if one further assumes that (b) the transmitter releases *exactly* N A molecules, and (c) the reception mechanism at the receiver can be described as a binary process (i.e., a molecule

is either counted or it is not counted), then, r follows a Binomial distribution with mean $\bar{r}$ and variance $\sigma_r^2 = \bar{r}(1 - \bar{h})$. The latter assumption is valid for all three considered receiver models. For example, for the passive receiver (fully absorbing receiver) at any time t , a given A molecule is either inside the volume of the receiver (absorbed) or not. Similarly, for the reactive receiver, at any time t , a receptor B molecule is either activated (i.e., a C molecule is formed) or it is not activated. Thus, $f(r)$ can be written as follows

$$\begin{aligned} r &\sim \text{Binomial}(N, \bar{h}), f(r) \\ &= \binom{N}{r} (\bar{h})^r (1 - \bar{h})^{N-r}. \end{aligned} \quad (13)$$

The Binomial distribution complicates the analysis of MC systems. As a result, two approximations of the Binomial distribution are commonly used for analysis:

- **Gaussian Distribution:** Under the assumption that $\bar{r}$ is sufficiently large for the central limit theorem to apply, r can be modeled as a Gaussian random variable with mean $\bar{r}$ and variance $\sigma_r^2 = \bar{r}(1 - \bar{h})$, i.e.,

$$\begin{aligned} r &\sim \mathcal{N}(\bar{r}, \bar{r}(1 - \bar{h})), \\ f(r) &= \frac{1}{(2\pi\bar{r}(1 - \bar{h}))^{1/2}} \exp\left(-\frac{(r - \bar{r})^2}{2\bar{r}(1 - \bar{h})}\right). \end{aligned} \quad (14)$$

The Gaussian distribution is much more amenable to analysis than the Binomial distribution. It is worth mentioning that the accuracy of the Gaussian distribution relies on basic assumption that $\bar{r}$ is large, i.e., the received signal is strong.

- **Poisson Distribution:** The Binomial distribution can be approximated by a Poisson distribution if N is very large and $\bar{h}$ is very small. Both of these assumptions usually hold for diffusive MC systems. Thus, we can write

$$r \sim \text{Poiss}(\bar{r}), \quad f(r) = \frac{\bar{r}^r \exp(-\bar{r})}{r!}. \quad (15)$$

Receiver Mechanisms for Synthetic Molecular Communication Systems with Diffusion, Fig. 3 $\bar{r}$ versus time t for three different receiver models

Results and Discussions

For all simulation results, the following set of system parameters is considered: $d = 1$ [μm], $a = 0.25$ [μm], $N = 2000$, and $D = 5 \times 10^{-9}$ [m^2/s]. Moreover, the simulation results are obtained via standard particle-based simulation of Brownian motion.

Figure 3 shows $\bar{r}$ versus time t for the three considered receiver models. For the fully absorbing receiver, (5) with $t_u = t + \Delta t$, $t_l = t$, and $\Delta t = 6$ [μs] is employed. Furthermore, for the reactive receiver, $k_f = 4.68 \times 10^{-21}$ [$\text{molecule}^{-1} \cdot \text{m}^3 \cdot \text{s}^{-1}$] and $k_b = 8 \times 10^4$ [s^{-1}] are chosen. For all curves $k_d = 0$. Simulation results confirm the accuracy of the expressions reviewed in the previous sections. It can also be observed that all curves have similar shapes, i.e., first $\bar{r}$ increases, then it decreases.

Figure 4 shows $\bar{r}$ for the reactive receiver versus time t for different system parameters; $M = \{3000, 1000\}$, $k_f = \{4.68, 9.36\} \times 10^{-21}$ [$\text{molecule}^{-1} \cdot \text{m}^3 \cdot \text{s}^{-1}$], $k_b = \{8, 12\} \times 10^4$ [s^{-1}], and $k_d = 8 \times 10^3$ [s^{-1}]. Figure 4 shows that,

for given k_f and k_b , employing more receptors M increases $\bar{r}$. This was expected as increasing M increases the chance that a receptor is activated. It can also be observed that, for given k_b and M , a larger value of k_f increases $\bar{r}$ as the capture probability of the signaling molecules is increased. Furthermore, for given k_f and M , an increase in the value of k_b decreases $\bar{r}$, since for larger values of k_b , the unbinding reaction is more likely to happen and, as a result, more signaling molecules can dissociate and escape from the vicinity of the receiver.

In Fig. 5, the root mean squared error (RMSE) between the Gaussian/Poisson cumulative distribution function (CDF) and the Binomial CDF is plotted vs. $\bar{h}$. Figure 5 reveals that for increasing $\bar{h}$, the accuracy of the Poisson model deteriorates, whereas the accuracy of the Gaussian model improves. This behavior was expected from the assumptions needed for the validity of the approximate models. However, for typical diffusive MC systems, $\bar{h} \ll 0.1$ holds. As a result, the Poisson model is generally more accurate.

Reinforcement Learning-Based Wireless Communications Against Jamming and Interference

Liang Xiao

Department of Communication Engineering,
Xiamen University, Xiamen, China

Definition

Learning-based anti-jamming communication strategy applies reinforcement learning algorithms for mobile users in wireless networks to achieve the optimal transmission policy against jamming and interference, without knowing the network model, radio channel model, and jamming model.

Historical Background

Due to the broadcast nature of radio propagation, wireless networks are vulnerable to jamming attacks, as jammers purposefully inject replayed

or faked signals into wireless media to interrupt the ongoing radio transmissions between legitimate users (Xu et al. 2005; Xiao 2015). With the pervasion of smart and programmable radio devices such as universal software radio peripherals (USRPs) (Rahbari et al. 2016), smart jammers choose to launch multiple types of attacks, such as eavesdropping and spoofing attacks, and select the jamming power, frequency, and time against the ongoing wireless transmissions (Trappe 2015; Xiao et al. 2018a). Smart jammers can even analyze the ongoing anti-jamming transmission policy and induce the mobile devices to use a specific communication mode and then block them accordingly (Akyildiz et al. 2008; Xiao et al. 2015). Jamming attackers aim to degrade the communication efficiency of the ongoing transmission, increase power consumption of the radio nodes, and even lead to denial of services (DoS) attacks (Xiao et al. 2012a).

Traditional anti-jamming wireless communication solutions, spread spectrum techniques, such as frequency hopping and direct-sequence spread spectrum, have been used for decades to address jamming attacks in wireless networks (Xu et al. 2005; Wang et al. 2012; Xiao et al. 2013). However, significant challenges have to be addressed in 5G systems, e.g., spread spectrum technique requires both the transmitter and the receiver to share the physical-layer secrets such as the spreading codes or frequency hopping pattern in advance. However, jammers can derive the spreading codes of the transmitter by eavesdropping the public control channels and compromising cognitive radio nodes in large-scale dynamic wireless network (Attar et al. 2012).

Anti-jamming techniques such as uncoordinated frequency hopping (Liu et al. 2010; Xiao et al. 2012b) have been proposed to address these problems. However, many of these still suffer from low communication efficiency and high-energy cost in dynamic wireless networks (Li et al. 2010, 2012; Xiao et al. 2012c). In wireless communications, a mobile device has difficulty obtaining the network and jamming model, such as the channel condition, jamming, and interference strength in dynamic environments.

The transmission policy such as the transmit power and channel selection in a dynamic game among the mobile devices, jammers, and interference sources can be viewed as a Markov decision process (MDP) (Xiao et al. 2017, 2018b,c). Reinforcement learning (RL) techniques, such as Q-learning and DQN, can be used to find the optimal strategy in MDP via trial and error (Sutton and Barto 1998). Therefore, the channel selection based on Q-learning can improve the resistance against jamming (Conley and Miller 2013), and the channel accessing with Q-learning can address smart jammers in hostile environments (Gwon et al. 2013). Deep reinforcement learning technique, such as DQN, can accelerate the learning speed of mobile device to achieve the optimal anti-jamming strategy, in the environment with a large number of frequency channels (Han et al. 2017).

Foundations

We assume a wireless communication system using frequency hopping over N frequency channels. At time slot k , the mobile device chooses its transmission policy denoted by $x^{(k)} \in \{0, \dots, N\}$ and sends a message with power P_s on channel $x^{(k)}$. If $x^{(k)} = 0$, the mobile device leaves the area for better transmission condition. The mobile device observes the state at time k denoted by $\mathbf{s}^{(k)}$, which consists of the presence of the PUs, and the previous SINR, i.e., $\mathbf{s}^{(k)} = [\lambda^{(k-1)}, \text{SINR}^{(k-1)}]$.

The CNN is used to estimate the Q-value, denoted by $Q(\mathbf{s}^{(k)}, x)_{0 \leq x \leq N}$, for each action. The CNN consists of two convolutional (Conv) layers and two fully connected (FC) layers. The first Conv layer includes 20 filters each with size 3×3 and stride 1, and the second Conv layer has 40 filters each with size 2×2 and stride 1. Both Conv layers use the rectified linear unit (ReLU) as the activation function. The first FC layer involves 180 rectified linear units, while the second FC layer has $N + 1$ units for the action set. The filter weights of the four layers in the CNN at time k are denoted by $\theta^{(k)}$.

Let $\varphi^{(k)}$ denote the state sequence at time k , which consists of the current system state and the previous W system state-action pairs, i.e., $\varphi^{(k)} = [\mathbf{s}^{(k-W)}, x^{(k-W)}, \dots, x^{(k-1)}, \mathbf{s}^{(k)}]$. The state sequence is then reshaped into a 6×6 matrix as the input to the CNN to estimate $Q(\varphi^{(k)}, x|\theta^{(k)})$, $\forall 0 \leq x \leq N$. The CNN parameters $\theta^{(k)}$ are updated at each time slot based on experience replay.

The experience observed by the mobile device is denoted by $\mathbf{e}^{(k)} = [\varphi^{(k)}, x^{(k)}, u_s^{(k)}, \varphi^{(k+1)}]$, and the memory pool at time k is given by $\mathcal{D} = \{\mathbf{e}^{(1)}, \dots, \mathbf{e}^{(k)}\}$. The experience replay chooses an experience $\mathbf{e}^{(d)}$ from memory pool $\mathcal{D}$ at random, with $1 \leq d \leq k$ to update $\theta^{(k)}$ according to a stochastic gradient descent (SGD) algorithm. The mean-squared error of the target optimal Q-function value is minimized with minibatch updates, and the loss function is chosen by Mnih et al. (2015) as

$$L(\theta^{(k)}) = \mathbb{E}_{\varphi^{(k)}, x, u_s, \varphi^{(k+1)}} \left[\left(R - Q(\varphi^{(k)}, x; \theta^{(k)}) \right)^2 \right], \quad (1)$$

where R is the target optimal Q-function, which is given by

$$R = u_s + \gamma \max_{x'} Q(\varphi^{(k+1)}, x'; \theta^{(k-1)}). \quad (2)$$

The gradient of the loss function with respect to the weights $\theta^{(k)}$ is given by

$$\begin{aligned} \nabla_{\theta^{(k)}} L(\theta^{(k)}) &= \mathbb{E}_{\varphi^{(k)}, x, u_s, \varphi^{(k+1)}} \left[R \nabla_{\theta^{(k)}} Q(\varphi^{(k)}, x; \theta^{(k)}) \right] \\ &\quad - \mathbb{E}_{\varphi^{(k)}, x} \left[Q(\varphi^{(k)}, x; \theta^{(k)}) \nabla_{\theta^{(k)}} Q(\varphi^{(k)}, x; \theta^{(k)}) \right]. \end{aligned} \quad (3)$$

This process repeats B times at each time slot, and $\theta^{(k)}$ is updated according to the B randomly selected experiences.

By using the ε -greedy algorithm, the mobile device chooses the action $x^{(k)}$ according to the

Q-function and $\mathbf{s}^{(k)}$. If $x^{(k)}$ is 0, the mobile device leaves the area. Otherwise, the mobile device transmits the message on channel $x^{(k)}$. The BS estimates the SINR of the device signal and feeds it back to the mobile device. The mobile device evaluates the utility $u_s^{(k)}$ based on the SINR and the transmission cost. According to the next state sequence $\varphi^{(k+1)}$, the mobile device stores the new experience $[\varphi^{(k)}, x^{(k)}, u_s^{(k)}, \varphi^{(k+1)}]$ in the memory pool $\mathcal{D}$.

Key Application

The RL-based anti-jamming wireless communication scheme can be applied in mobile communications and Internet of things.

[Relays in LTE-Advanced](#)

Definition

Relaying and many other technologies have been standardized by Third-Generation Partnership Project (3GPP) in Release 10 of Long-Term Evolution (LTE) specifications, which results in huge performance enhancements compared to Release 9. To underline the major evolution, 3GPP approved LTE-Advanced as the official marker for Release 10 of LTE. In LTE-Advanced, relaying means that the eNodeB communicates with the user equipment (UE) with the help of a relay node (RN) wirelessly connected to the network. Specifically, the RN receives the RF signals transmitted from the eNodeB/UE and then forwards the processed signals to the UE/eNodeB.

Historical Background

With the increasing demand for high-rate applications and explosive growth in the number of UEs, the performance requirements of the wireless network, such as capacity and data rates, are much higher. One way of network performance enhancement is to deploy more eNodeBs. In this way, the distance between base stations and the distance between the eNodeB and the corresponding served UEs are both shortened which leads to higher data rates for each UE. However, to connect to the network, an eNodeB requires wired backhaul link such as an optical fiber, which results in a high-cost deployment and long construction period. Moreover, in some places, such as rural areas, deploying eNodeBs is not cost-effective as of which the functionality cannot be fully exploited due to the low population density. In order to alleviate the above problems in the deployment aspect, 3GPP considered relaying as one of the critical technologies of LTE-Advanced. 3GPP started relaying work item since January 2010 and standardized the corresponding specification at April 2011 (3GPP 2011a,b). Relaying work item was started from January 2010 and formally standardized in March 2011.

Relays can be classified in terms of a variety of criteria. According to the processing method for the received signals, relays can be classified as amplify-and-forward (AF) and decode-and-forward (DF) ones. AF relays amplify the received signals in radio frequency and then forward them to the destination node. DF relays decode and re-encode the received signals before forwarding them to the destination node. Note that, the noise and interference are also amplified along with the effective information components by using AF relays, which are eliminated by using the DF ones. According to the operating bands used by the transmitter and the receiver, relays can be classified as out-band and in-band ones. For the out-band relays, the transmitter and the receiver in the relay operate on different frequency bands. The main advantage of out-band relays is to support full-duplex operation, i.e., out-band relays can simultaneously transmit and receive signals, as long as the separation in the frequency domain of the transmission and reception links is large enough so that there is no interference with each other. Moreover, out-band relays can be integrated into the network without any modification of the radio interfaces of the previous release eNodeBs and UEs. However, the costs of network operation are increased due to the additional required spectrum. For the in-band relays, the transmission and reception links operate in the same frequency band. For this case, time division multiplexing should be used for the two links to make sure that only one link is active at a given time, i.e., half-duplex, thereby avoiding interference with each other. It should be noted that full-duplex operation can still be achieved for the in-band relays by physically isolating between the antennas of the transmitter and receiver in in-band relays. However, the overall costs will be increased seriously. By August 2009, 3GPP identified two types of RN, i.e., type-1 RNs and type-2 RNs during the research term of LTE-Advanced relaying. Both types of RN are DF relays. The main difference between the two types is whether they are transparent to the served UEs. A type-1 RN has its own physical cell ID (PCI, defined in LTE Release 8) and generates a new cell different from the linked donor eNodeB

cell. A type-1 RN independently generates cell control signaling and transmits scheduling information to the served UEs. Therefore, from UEs' point of view, a type-1 RN acts as a separate eNodeB distinct from the donor cell. Also, a type-1 RN should act as if it is a Release 8/9 eNodeB to the Release 8/9 UEs with the aim of backward compatibility. A type-2 RN cannot generate its own PCI and therefore share the same PCI used by the donor eNodeB. A type-2 RN is used only for the physical downlink shared channel (PDSCH) transmission since it cannot generate cell control signaling and does not have its own scheduler. The primary application of type-2 RNs is the cooperative relaying (Dohler and Li 2010).

In LTE-Advanced, the relaying standardization mainly focuses on the in-band half-duplex type-1 RNs. In the context of LTE-Advanced and from a functional perspective, an RN can be seen as an eNodeB with the functionality of wireless backhauling. Explicitly, RNs wirelessly connect to the network using LTE radio-access interface technologies which allow RNs to be deployed quickly and with lower costs. However, the wireless backhauling also brings some disadvantages to RNs compared to eNodeBs. The overall delay between the eNodeB and the UEs served by an RN is increased due to the wireless backhaul propagation. Meanwhile, since the access resource is shared between the backhaul link and access link – the link between the RN and the UE served by the RN, the RN can use only partial access resource to avoid self-interference and therefore offers a smaller capacity than one eNodeB.

A typical RN deployment scenario is shown in Fig. 1. The donor eNodeB can only provide

services to the UE located in the donor eNodeB cell, i.e., UE1. To offer services to UE2 located out of the donor eNodeB cell, an RN can be deployed by the network operator at a place in the donor eNodeB cell so that UE2 is located in the RN cell. An RN communicates with the donor eNodeB via backhaul link, which is also referred to as Un interface (3GPP 2015), and communicates with a UE via access link which is also referred to as Uu interface. The term “donor” in front of eNodeB implies that the eNodeB shares partial radio resources belonging to the UEs located in the eNodeB cell to RNs for servicing UEs out of the eNodeB cell. To seamlessly integrate RNs into the implemented LTE networks, 3GPP considered the backward compatibility with the previous release eNodeBs as the primary requirement, which will be further discussed in section “Foundations.”

Foundations

The overall architecture of LTE-Advanced relaying is illustrated in Fig. 2. Both eNodeB and donor eNodeB are connected to the mobility management entity (MME) and serving gateway (S-GW) units of the core network via S1 interface. X2 interface provides a connection between eNodeBs. The first requirement of relaying standardization is backward compatibility with Release 8/9 UEs; that is, there is no difference between connecting an RN or an eNodeB from the perspective of UE1. Therefore, an RN has all the functionality of an eNodeB. As shown in Fig. 2, the access link between the RN and UE1 also follows the same Uu interface specification

Relaying in LTE-Advanced, Fig. 1 A typical RN deployment scenario

**Relaying in
LTE-Advanced, Fig. 2**
Overall relay architecture

used for the connection between UE2 and the eNodeB. An RN also has the basic functionality of a UE along with relay-specific enhancements to ensure that the RN can communicate with the donor eNodeB via the Un interface. In order to communicate with other nodes of the network such as eNodeBs, MME, and S-GW, an RN needs the S1 and X2 interfaces, which are offered by the donor eNodeB via the Un interface. Therefore, the donor eNodeB acts like a proxy between the served RN and the rest of nodes of the network. From the perspective of the core network, it looks like UE1 is directly connected to the donor eNodeB. From the perspective of the RN, it looks like the RN communicates with the core network directly. Also, for the X2 interface proxy, the donor eNodeB is also transparent as if the RN communicates with the other eNodeB via the X2 interface. The RN acts like the donor eNodeB toward the served UE and acts like the served UE toward the donor eNodeB. Therefore, the RF requirements for the LTE-Advanced RN are similar to those of an eNodeB on the access link and those of a UE on the backhaul link (3GPP 2012, 2017a,b).

For the in-band relaying scenario, RNs cannot simultaneously transmit and receive signals for avoiding mutual interference. In LTE-Advanced,

RNs exploit time division multiplexing between the transmission of the backhaul and access links. Therefore, the UE-to-RN transmission is not allowed at the subframe that the RN takes for transmitting signals to the donor eNodeB. For this purpose, the uplink scheduler in the RN can be used to ensure that the access link is not activated for such subframe. According to a similar principle, the RN can only receive signals from the eNodeB for the subframe where no RN-to-UE transmission takes place. However, Release 8/9 UEs at least expect the synchronization signals and reference signals (CRS) in each subframe from the access downlink transmission to keep the connection with the RN. To simultaneously keep compatible with the Release 8/9 UEs and receive signals from backhaul downlink, RNs can adopt multicast-broadcast single-frequency network (MBSFN) subframe, which is defined in the previous release of LTE for supporting multimedia broadcast/multicast service. Release 8/9 UEs can recognize the MBSFN subframe where the first or two OFDM symbols are referred to as the control region and the remaining symbols are referred to as the MBSFN region. An RN can then use an MBSFN subframe to transmit at least synchronization signals and CRS to the UES in the control region and then receives the donor-to-RN transmission in the

Relaying in LTE-Advanced, Fig. 3 Time division multiplexing between backhaul and access links

Relaying in LTE-Advanced, Fig. 4 A typical usage of R-PDCCH

MBSFN region, as shown in Fig. 3. The subframe type used by the UE, i.e., normal and MBSFN subframe, is scheduled by the radio resource control signaling.

The time-frequency resource blocks (RBs) used for the necessary downlink control information and the RBs used for paging information and data transmission are, respectively, defined as physical downlink control channel (PDCCH) and PDSCH. The RN cannot receive the L1/L2 control signaling transmitted from the eNodeB in the PDCCH using the OFDM symbols in the control region of the MBSFN subframe, which is already occupied by the RN-to-UE synchronization signals and CRS transmission. To cater for this, 3GPP introduced an RN-specific PDCCH, i.e., R-PDCCH in Release 10 of LTE. R-PDCCH is transmitted using the OFDM symbols in the MBSFN region of the MBSFN subframe and therefore should be multiplexed with PDSCH. A typical usage of R-PDCCH is shown in Fig. 4. The downlink assignment to the RN is transmitted in the first time slot of the MBSFN subframe. On the other hand, the low time-priority uplink grant is located in the second time slot since the uplink transmission is later than downlink. When no uplink grant needs to be

transmitted, the second time slot can be utilized for PDSCH transmission from the eNodeB to the RN.

Key Applications

RNs can be used as eNodeBs for coverage extension and capacity enhancement. Also, wireless backhauling makes RNs suitable for many application scenarios because of the advantages of flexible deployment and cost-effective implementation. The typical application scenarios are displayed as follows (Yuan 2012):

- *Rural area.* The required traffic volumes in rural area are usually small due to the low population density. From a network operator's point of view, instead of deploying eNodeBs, deploying RNs for covering such area is a better choice as it can reduce the costs of deployment without degrading the quality of service. In this case, coverage extension is the primary concern as shown in Fig. 5a.
- *Hot spot.* The network operator can deploy RNs in outdoor/indoor hot spots for capacity enhancement to support a satisfactory service

Relaying in LTE-Advanced, Fig. 5 Key application scenarios

experience (throughput) for the UEs in such places, as shown in Fig. 5b. The transmission power of RNs should keep low to reduce interferences to other cells.

- *Dead spot.* In urban areas, UEs may be located in a shadowing area due to high-rise buildings. For this case, RNs can be deployed to eliminate such coverage holes by forming line-of-sight backhaul and access links as shown in Fig. 5c.
- *Wireless backhaul.* For areas with low spectrum utilization, such as mountainous and rural areas, RNs can be deployed for wireless backhauling, i.e., the eNodeB-to-eNodeB communication as shown in Fig. 5d.
- *Temporary coverage.* Due to the characteristics of wireless backhauling, RNs are suitable for temporary radio coverage. Note that, deployment flexibility can be further enhanced by omitting the wired power connection by means of wireless energy harvesting technology (Zhang and Ho 2013).
- *Group mobility.* Due to the Doppler effects, mobile UEs in a bus communicate with the eNodeB via fast-fading channels and therefore consume more power to maintain a satisfactory data rate (Wu and Fan 2016). As shown in Fig. 5e, an RN can be mounted on the roof of the bus to provide static and stable access link for all the onboard UEs and hence save their battery consumption.

Relay-Aided Device-to-Device (D2D) Communications; Relay-Assisted D2D Communications

Definitions

D2D communication enables direct data transmissions between two D2D-capable user equipments (UEs) bypassing base station (BS) in Long-Term Evolution (LTE) systems. It can also be called direct D2D communication. Note: in the following text, evolved Node B (eNB) is used to replace the expression of BS.

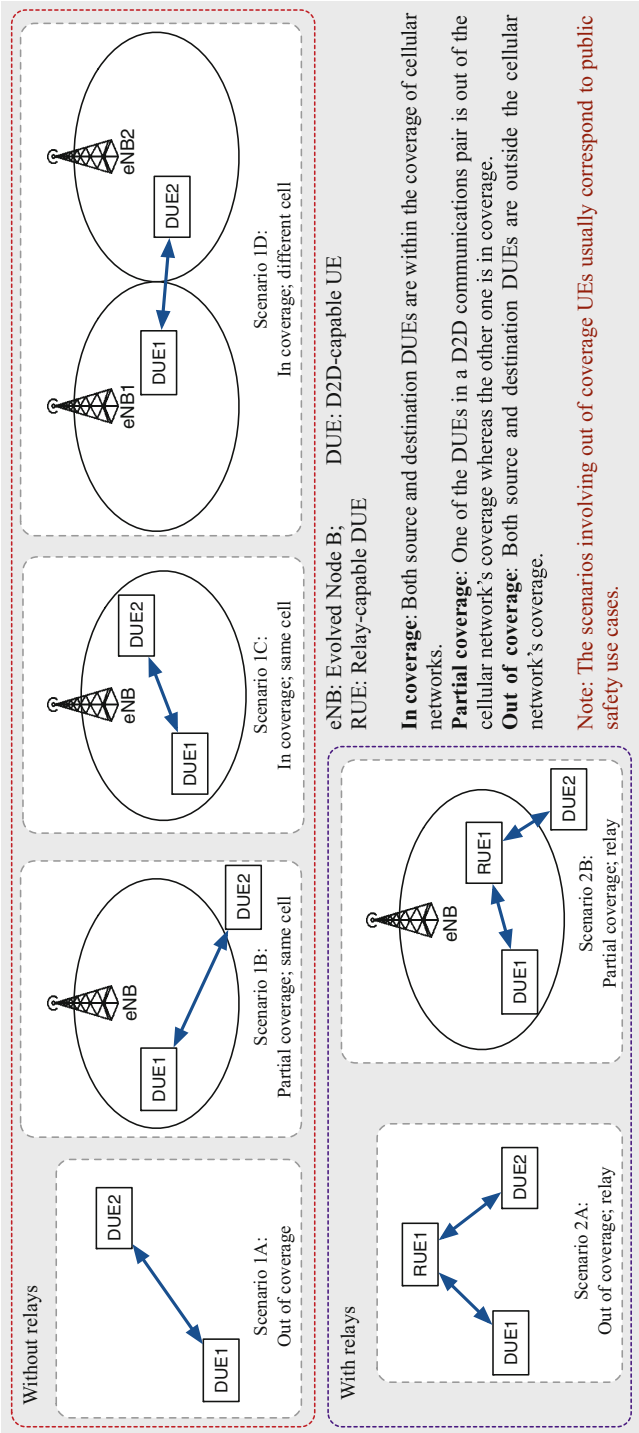

Relay-involved D2D communication encourages two D2D-capable UEs (DUEs) to communicate with each other via a relay node, which can be considered as a broad sense D2D communication. It extends the range of direct D2D communication.

Background

The concept of D2D communication was first proposed in Lin and Hsu (2000) to depict the direct data transmission between neighbor UEs on a multi-hop relaying link in cellular networks. Later on, the potential of using D2D communication to improve spectrum efficiency and system capacity of cellular networks was investigated. In the most typical research by Doppler et al. (2009), D2D communication was first treated as an underlay to LTE-Advanced (LTE-A) networks, in which mechanisms for D2D communication setup and management

involving procedures in the LTE system architecture evolution were proposed, and including D2D communication can increase the cell-wise throughput was proved. Soon after, other potential D2D use cases were identified, such as contents sharing, peer-to-peer data exchanging (Lei et al. 2012), UE-to-eNB data relaying, and so on. The first testbed for integration of D2D communication into a cellular network was the FlashLinQ built by Qualcomm, which is actually a physical (PHY)/media access control (MAC) architecture for D2D communications underlaying cellular networks (Asadi et al. 2014). By the use of orthogonal frequency division multiplexing/orthogonal frequency division multiple access (OFDM/OFDMA) and distributed scheduling, FlashLinQ provides researchers reference solutions for efficient proximity discovery, timing synchronization, and link management in D2D-involved cellular networks. These researches prove that not only can D2D communication improve the entire system spectral efficiency via flexible reuse of radio resources but also ease the core network data processing loads by performing traffic offloading. Besides, the Third Generation Partner Project (3GPP) has also started the discussions on developing D2D communications as proximity services (ProSe) in LTE networks, and Fig. 1 shows the D2D scenarios taken into account by the 3GPP standardization group (Mach et al. 2015).

D2D communication can be classified into licensed-band D2D and unlicensed-band D2D. The unlicensed-band D2D communication is performed based on other wireless network standards operating on unlicensed radio resources, which can support direct communications, such as Wi-Fi Direct. It can be realized either in the network-controlled manner or in the autonomous manner. The licensed-band D2D communication takes place on the licensed cellular radio resources allocated by the core network. Licensed-band D2D communications are all in network-controlled manner and can be further divided into dedicated (i.e., overlay) and reuse (i.e., underlay) modes. The former works in a way that D2D UEs operate on

Relay-Involved Device-to-Device Communications in LTE Networks, Fig. 1 3GPP D2D communication scenarios

separated cellular resources, whereas the latter requires that D2D UEs share the same cellular resources with general cellular UEs (CUEs). In dedicated mode, there is no interference between D2D and cellular UEs, due to the fact that eNB assigned orthogonal channels for D2D and cellular links. In reuse mode, there are co-channel interferences between D2D and the shared cellular links, which means that eNB should keep such interference lower enough to ensure the quality of service (QoS) of both D2D and the shared cellular links when performing joint scheduling on resource allocation and power control. Working on unlicensed bands is commonly subject to uncontrolled interference from coexistence systems. Hence, majority of the existing research focused on licensed-band D2D communications within a single cell environment just as Scenario 1C in Fig. 1, aiming to improve spectrum efficiency and cell-wise data transmission performance by encouraging flexible resource allocation and communication mode selection (Fodor et al. 2012; Min et al. 2011; Yu et al. 2014). These works usually assume three communication modes for D2D-capable UEs, i.e., general cellular mode, dedicated D2D mode, and reuse D2D mode, as shown in Fig. 2. The dedicated mode only utilizes traffic offloading capability of D2D communications, whereas the reuse mode could further obtain channel reuse gain. Note that it is suggested that D2D UEs in reuse mode should reuse the cellular uplink resources to avoid the interference from eNB.

Both dedicated and reuse D2D modes in existing works actually belong to direct D2D mode, i.e., the source and destination DUEs perform direct communication with each other. Only using direct D2D mode may limit the benefits brought in by D2D communications to LTE systems, because sometimes source and destination DUEs may not be able to perform direct D2D communications due to long separation distance and poor channel condition between them (Hasan et al. 2014). In such cases, a promising way to fully explore the benefits of D2D communications is to enable eNB-controlled D2D transmissions through relays,

which can substantially extend the range of D2D communications (Ni 2016).

Bringing relay technologies into D2D communications offers DUEs more opportunities to work on D2D mode in a cellular network, and it can be regarded as a supplement/enhancement to direct D2D. Currently, the research in this area is still in its initial exploratory stage. This work tried to offer audiences a short overview on the current research on relay-involved D2D communications.

Potential Relay-Involved D2D Communications

In existing research focusing on the D2D communication with relay assistance, the relay node can be either relay-capable UEs (RUEs) or fixed relay stations. Hasan et al. (2014) investigated D2D communications served by fixed location LTE-A Layer-3 (L3) relay stations, which can relay not only data from faraway UEs to eNB but also data between source and destination DUEs. They mainly discussed the radio resource and power allocation problem at the relay node when the data from UE to eNB and from source DUE to destination DUE are simultaneously relayed. eNB can also be treated as a relay. Ma et al. (2017b) proposed local route mode as another D2D communication mode, in which the source and destination DUEs communicate with each other using eNB as their relay station, but the data will not go through the core network. Here eNB acts as only a relay station with scheduling capability. But RUE-assisted D2D communications may be more flexible due to an explosive increase in UE density in LTE systems. Hence most works in this area considered the “relays” in relay-involved D2D communication as RUEs. Some literatures called relay-involved D2D communication as two-hop D2D, which can be further classified into two types. The first type demonstrates that a DUE in/out of a eNB’s coverage communicates with the eNB via relay-capable DUE’s relaying with an aim to enhance the transmissions to/from eNB or extend the coverage of eNB (Nishiyama et al. 2014; Liu and Kato

Relay-Involved Device-to-Device Communications in LTE Networks, Fig. 2 Three typical communication modes for DUEs in existing literatures

2015), whereas the second type demonstrates that two DUEs within an eNB's coverage may communicate with each other via the help of a relay-capable DUE under the eNB's control when direct D2D cannot meet the QoS requirements (Wei et al. 2016; Ma et al. 2012). Actually, in the first type two-hop D2D, there is only one hop transmission (i.e., DUE to/from relay) on the DUE-relay-eNB link strictly belonging to D2D communications, and the other hop transmission (i.e., Relay to/from eNB) is just same as the cellular uplink or downlink communication. In strict sense, it cannot be called two-hop D2D. Thus, this work focused on introduction of two-hop D2D belonging to the second type, in which both source and destination nodes are DUEs.

According to different relaying schemes adopted, the research on relay-involved D2D communications can be highlighted and summarized from the following four directions:

- *Single-way relay-assisted D2D communication*: It demonstrates that two DUEs communicate with each other with the help of a selected RUE, under which a complete single-way end-to-end data transmission is finished in two time slots (Ma et al. 2012, 2017a). The source-to-relay and relay-to-destination transmission are sequentially performed. The selected RUE receives the signals transmitted from source DUE in the first time slot and makes necessary processing, and then it transmits the processed

signals to destination DUE. eNB can allocate the source-to-relay and relay-to-destination links either the same radio resources or the different radio resources. Relay-assisted D2D communication can also be classified into dedicated mode and reuse mode according to whether it is permitted to share the CUEs' channels. Figure 3 shows four potential modes for single-way relay-assisted D2D communications, i.e., dedicated/reuse single-way relay D2D and dedicated/reuse single-way cooperative D2D. In the reuse single-way relay D2D mode of Fig. 3, the source-to-relay and relay-to-destination D2D links reuse the same cellular uplink channel, i.e., CUE2's uplink channel. Hence, in the first hop transmission, the receiving relay node, RUE1, suffers interference from CUE2, and the CUE2's uplink transmission suffers interference from the source DUE, i.e., DUE1, whereas in the second hop transmission, the interference links are just from CUE2 to the receiving DUE2 and from the transmitting RUE1 to the receiving eNB. The cooperative D2D mode can be considered as a further enhancement to the corresponding relay D2D mode, under which the source DUE transmits desired signals to the relay node and destination DUE simultaneously in a broadcasting manner in first transmission time slot and, in the second transmission time slot, the relay node will also transmit the received signals to the destination DUE. Here, after

Relay-Involved Device-to-Device Communications in LTE Networks, Fig. 3 Single-way relay-assisted D2D communication modes

R

receiving both signals from the relay link and direct link, destination DUE will make a combination processing to them to strengthen the desired signal. Typical combining methods include maximum ratio combining and equal gain combining.

- *Full-duplex relay-assisted D2D communication:* It demonstrates that in the source-relay-destination D2D link, the selected RUE works in a full-duplex manner, meaning that the relay node is capable of performing signal receiving and transmitting at the same time (Wang et al. 2015). Thus, the data transmission from source to destination DUEs via a full-duplex RUE can be finished within only

one time slot, i.e., the source-to-relay and relay-to-destination transmissions take place simultaneously. In such full-duplex relaying scenarios, the source-to-relay and relay-to-destination links are commonly assigned the same radio resources, and this leads to new interferences, including self-interference at the relay node and the interference from source DUE to destination DUE, as depicted in Fig. 4, which shows the potential dedicated and reuse full-duplex relay-assisted D2D communication modes. In the reuse full-duplex relay D2D mode of Fig. 4, the uplink channel of CUE2 is reused by entire relay link, and all the potential interferences occur

Relay-Involved Device-to-Device Communications in LTE Networks, Fig. 4 Full-duplex relay-assisted D2D communication modes

in the same time slot. Apparently, to ensure the QoS requirements for both D2D and cellular links in full-duplex relaying scenarios, eNB needs to be equipped with more complicated scheduling schemes for efficient interference control.

- *Two-way relay-assisted D2D communication:* It demonstrates that in the relay-assisted D2D path, the selected RUE simultaneously receives the signals from source and destination DUEs just like a multiple access process and directly makes a summation to the two signals in the first transmission time slot, and then in the second transmission time slot, the selected RUE broadcasts the combined signal to the source and the destination DUEs (Wei et al. 2016; Ni et al. 2014; Ni 2016). Note that the source and the destination DUEs should transmit their data simultaneously to the relay, and before broadcasting, the relay node may scale the combined signal to ensure the QoS requirements. Once the source and destination DUEs receive the broadcasted signal from the relay node, each of them can acquire its desired term by canceling the self-interference term, since they know their transmitted signals, respectively. Hence, with this relaying scheme, a complete data

exchange between the source and destination DUEs can be finished within only two time slots. According to whether reusing the CUEs' channels, two-way relay-assisted D2D communication can also be classified into dedicated and reuse modes, as shown in Fig. 5. In dedicated mode, same radio resources are assigned to all the transmission links in the two time slots. In reuse mode, the source-to-relay and the destination-to-relay links in the first time slot are assigned the same radio resources, but the radio resources used in the first and the second time slots can be either the same or different. The reuse mode in Fig. 5 shows audiences the situation that the transmissions in the first and the second time slots are reusing the same cellular uplink resources. The interference graph under the reuse mode is clear: in the first time slot, the relay node will receive interference from the CUE whose uplink channel is reused and eNB will simultaneously receive the interferences from both the source and destination DUEs, while in the second time slot, both the source and destination DUEs will be interfered by the CUE whose uplink channel is reused and the eNB will be interfered by the relay node. It should be stated that to realize such

two-way relay-assisted D2D transmissions, more efficient and precise timing management schemes should be designed for eNB, which definitely will increase the system complexity.

- *Network coding (NC)-based relay-assisted D2D communication:* It usually demonstrates the scenarios that multiple D2D communication pairs share the same relay node (Zhao et al. 2017) or one D2D communication

pair performs data exchange using multiple relay nodes at the same time (Huang et al. 2017). Taking the scenario that one D2D communication pair with multiple relay nodes for an example, its data exchanging process, when reusing cellular uplink resources, can be depicted as Fig. 6, in which all the transmission links in the two time slots reuse the same CUE’s uplink channel. Note that radio resource allocated for the transmission

Relay-Involved Device-to-Device Communications in LTE Networks, Fig. 5 Two-way relay-assisted D2D communication modes

Relay-Involved Device-to-Device Communications in LTE Networks, Fig. 6 NC-based relay-assisted D2D communication in reuse mode

R

links in the first time slot can be different from that in the second time slot. It depends on the eNB's scheduling. NC-based relay-assisted D2D communication can also be classified into dedicated and reuse mode according to whether performing channel reuse. Only the reuse mode is introduced here. As shown in Fig. 6, in the first transmission time slot, the source and destination DUEs simultaneously broadcast their signals to all the selected RUEs, and each relay will encode its received data packets. One of the most simple encoding methods is encoding the data packets via XOR operation. The amount of packets encoded at a relay node is just the number of data packets received from DUE1 and DUE2. This is exactly the coding process in the so-called "NC". Due to reuse of the uplink channel of CUE2 by D2D links, DUE1 and DUE2 will cause interference to the cellular uplink, and the relay node will also receive interference from CUE2. In the second transmission time slot, all relay nodes broadcast their encoded data packets to DUE1 and DUE2, which will then perform packets decoding by using their transmitted data packets in the first time slot. The amount of decoded data packets of DUE1, with respect to only one relay node, is the minimum between the packet transmission rate on this relay to DUE1 link and the amount of this relay node's encoded packets in the first time slot. The total amount of decoded data packets of DUE1, respecting to multiple relay nodes, is the sum of the amounts of DUE1's decoded data packets with respect to each relay node. The amounts of DUE2's decoded data packets can be understood in a similar way. The corresponding interferences include the inferences from relay nodes to eNB and from CUE2 to both DUE1 and DUE2. Obviously, it requires new design for the eNB's scheduling to support such a complicated communication process. In addition, it can be easily identified that the aforementioned two-way relay-assisted D2D communication can be considered as a one-relay case of the NC-based relay-assisted D2D communication.

Overall, exiting research on the four directions of relay-assisted communications is still in the stage of performance exploratory. These relay-assisted D2D communication modes have not been taken into account as candidate D2D modes in the mode selection procedure, and they were usually researched from the perspective of end-to-end transmission performance analysis. Furthermore, comparing the four types of relay-assisted D2D communication, it can be easily concluded that full-duplex, two-way, and NC-based relay-assisted D2D modes correspond to more complicated interference control and timing management, which will further increase the degree of difficulty on joint scheduling scheme design at the eNB side. In this respect, single-way relay-assisted D2D modes may be more implementable.

Key Applications

Typical use cases for relay-involved D2D communications may include traffic offloading, contents sharing, local voice service, machine-to-machine (M2M) communication, vehicle-to-vehicle (V2V) communication, and so on.

Key Research Challenges

Due to an explosive increase in both types and amounts of wireless devices, it is still a widely open issue to realize the relay-involved D2D communication modes in LTE networks, and the current LTE standard does not support them. Specifically, to support each of the aforementioned relay-assisted D2D modes raises up a lot of new issues on protocol-level design of an LTE network. The challenges come in three aspects.

- New radio protocol architectures (RPAs) should be designed for both DUEs and RUEs to support relay-assisted D2D modes. Perhaps, RPA design for direct D2D mode can refer to the existing PC5 interface for Proximity Service (ProSe) direct communications in

LTE-A. However, none of the existing releases of the LTE-A standard provided a definition level reference for the RPA design in relay-involved D2D modes.

- An efficient link-quality measurement and report strategy is needed to help the eNB performing control and scheduling on DUEs and RUEs. The involvement of relay-assisted D2D modes makes link-quality assessment and report procedures even more complex. Thus, how to design a precise and low signalling overhead strategy on link-quality measurement and report is critical.
- Scheduling algorithm at eNB should be redesigned to support communication mode selection for all DUEs. In current LTE system designs, the eNB needs only to perform scheduling on radio resource allocation and power control for all its UEs in each subframe. However, if all the related D2D modes are supported by most of the UEs in the next release of LTE-A standard, it will require that the eNB should be able to perform joint scheduling on communication mode selection (including relay selection for the relay-assisted D2D modes), resource allocation, and power control for all DUEs in each subframe to ensure an acceptable system performance.

Definition

Resource allocation in Industrial IoT is the joint design and optimization of network resources in multiple domains (frequency, time, power, and so on) to provide better services for different industrial applications.

Historical Background

The Internet of Things (IoT) provides a bridge between sensors, controllers, and actuators to enable the ultra-reliable low-latency communication services for control applications in industrial automation (Zhu et al. [2014](#); Lyu et al. [2016](#), [2018a](#); Stojmenovic [2014](#); Cheng et al. [2016](#), n.d.; Chen et al. [2015](#)). The emerging IoT has a wide range of applications in many fields, such as manufacturing, oil and gas, energy mining, metals, and other industrial sectors (Lyu et al.

2017; Zhang et al. 2017a, b; Guo et al. 2017; Lyu et al. 2018b).

Industrial IoT can improve interconnectivity, flexibility, scalability, time efficiency, cost effectiveness, security, productivity, and operational efficiency in the industries (Raza et al. 2017). IoT can also serve as a platform to establish intelligent network of devices (Gubbi et al. 2013) which can interrelate data and processes to effectively establish feedback control systems for industrial automation.

According to Li et al. (2018), IoT will support the integration of approximately 5.5 million things every day by 2016, with estimation of 20.8 billion things by 2020. The rapid increase of IoT machines brings some technical challenges in order to meet the complex requirements. For example, the existing wireless communication technologies with low power are still under investigation to meet the energy efficient requirement with high system reliability. Therefore, research efforts should be carried out to tackle the obstacle of industrial IoT to be deployed in practice, especially in industrial applications (Al-Rubaye et al. 2017). Industrial IoT is a specific branch of IoT which addresses the communication and connectivity issues in industrial environments and offers suitable solutions. Among all possible wireless communication network solutions for IoT, 5G is considered as a promising technology, which integrates entities, communications, and control technologies (Atat et al. 2017).

Since 5G supports enhanced mobile broadband communications, ultra-reliable and low-latency communications (URLLC), and massive machine-type communications (mMTC), it is clear that URLLC and mMTC in 5G are closely related to industrial IoT. Thus, 5G provides an ideal platform for communications in industrial IoT. In the application area of industrial automation, industrial IoT performs system monitoring and control with the assistance of 5G systems (Holfeld et al. 2016; Shariatmadari et al. 2015). In such a 5G-enabled industrial IoT, one major technical challenge is the resource allocation in industrial IoT, which takes charge of designing resource-efficient communication to facilitate various resources while providing

the satisfactory quality of service as well as supporting dynamic network environments and control systems.

Foundations

For the industrial IoT, the control system stability is severely affected by the wireless transmission reliability, which in turn relies heavily on the scheduling of limited wireless communication resources, such as channel, time, and power. The control system stabilization is regarded as the quality of performance requirement in the application layer, which can be mapped into a certain quality of service requirement in the lower layers. In this way, the desired quality of performance requirement can be achieved with proper resource allocation schemes, i.e., wireless transmission is regarded as another degree of freedom to be optimized in the industrial IoT system. Therefore, it is crucial to investigate the resource allocation for industrial IoT to improve the control-communication performance.

Therefore, it is important to achieve a dynamic and efficient resource allocation to cope with packet loss, delay, and other serious issues. To address this issue, the following foundations are necessary.

Dynamic Priority-Based Resource Allocation

In general, an industrial process includes multi-class traffics, such as emergency traffic, regulatory control traffic, alerting traffic, monitoring traffic, and so on. Different traffic usually has different importance. In this regard, the priority-based communication provides a better chance at the effective data transmission. However, the general use of predefined traffic priority may not be a suitable solution, since the priority of traffic in industrial networks changes on runtime, depending on variations in sensor readings. Hence, the widely proposed priority-based MAC protocols are inefficient in the scenario where certain variation in the existing priority may occur. As a solution, a more effective way to deal with processes like these is by establishing dynamic

priority, which could prioritize in real time. The concept behind dynamic priority scheduling is to form adaptive and evidence-based decision of which information is more critical and must be delivered on priority. Inclusion of dynamic priority scheduling meets the challenges of time constraint and information priority scheduling by efficiently sacrificing the resource of low priority data traffics.

Energy Efficiency

As many industrial IoT applications need to run for years on batteries, it creates a demand for energy-efficient designs. To complement such designs, upper-layer approaches play important roles through energy-efficient operation. Many energy-efficient schemes have been proposed in recent years (Rault et al. 2014), but those approaches are not immediately applicable to industrial IoT. Industrial IoT applications typically need a dense deployment of numerous devices. Sensed data can be sent in queried form or in a continuous form which in a dense deployment can consume a significant amount of energy. Green networking is thus crucial in industrial IoT to reduce power consumption and operational costs. It will lessen pollution and emissions and make the most of surveillance and environmental conservation. Although there are numerous methods to achieve energy efficiency, such as using lightweight communication protocols or adopting low-power radio transceivers as described above, the recent technology trend in energy harvesting provides another fundamental method to prolong battery life. Thus, energy harvesting is a promising approach for the emerging industrial IoT.

Timing and Reliability

Industrial IoT devices are typically deployed in noisy environments for supporting mission- and safety-critical applications, and have stringent timing and reliability requirements on timely collection of environmental data and proper delivery of control decisions. The QoS offered by IIoT is thus often measured by how well it satisfies the end-to-end deadlines of the real-time sensing and control tasks executed in the system (Ferrari et al.

2018; Zheng et al. 2016). Time-slotted packet scheduling in industrial IoT plays a critical role in achieving the desired QoS. For example, many industrial IoT systems perform network resource allocation via static data link layer scheduling (Leng et al. 2014; Saifullah et al. 2015) to achieve deterministic end-to-end real-time communication. Such approaches typically take a periodic approach to gather the network health status, and then distribute the updated network schedule information. This process however is slow, not scalable, and incurs considerable network overhead. The explosive growth of industrial IoT applications especially in terms of their scale and complexity has dramatically increased the level of difficulty in ensuring the desired real-time performance. The fact that most industrial IoT must deal with unexpected disturbances further aggravate the problem.

Key Applications

In general, industrial network system consists of spatially distributed sensors and multiple edge and/or remote estimators/controllers. Sensors cooperatively monitor physical system states or environmental conditions and estimators perform situation awareness and system control in a coordinated way.

Situation Awareness

One main application of resource allocation in the industrial IoT is the situation awareness, which aims to estimate the state parameters to understand the situation of sensed environment. However, sensors are generally powered with batteries and wireless spectrum resource is scarce. The limited energy and spectrum resource makes the functionalities of industrial IoT systems on sensing, transmitting, and control quite restricted. The potential contradictions between estimation accuracy and resource limitation motivate the investigation of resource allocation and state estimation co-design strategy. Therefore, it is important and necessary to properly assign various resources under the consideration of state estimation performance to improve the estimation performance in

a resource-efficient way, which could be achieved by investigating an energy-efficient communication and estimation co-design strategy for industrial IoT.

However, for the considered monitoring application in IIoT systems, the measurements obtained by nearby sensors have much similar information, resulting in high measurement-correlation. In addition, a large number of sensors, which are deployed to achieve the ubiquitous situation awareness, may cause problems in the connection establishment and radio resource allocation. In order to provide the required quality of experience for the monitoring application, besides the usually considered energy consumption, more application-centric performance metrics should be taken into account. However, this is challenging in the dynamic industrial environment, since wireless signals may suffer from severe fading, shadowing, multi-path propagation, and interference, due to obstructions from big metal equipments, movements of machineries, electromagnetic interferences, high temperatures and humidities, and so on (Vitturi et al. 2013).

Recently, the hierarchical framework combining with centralized and distributed state esti-

mations has been studied for guaranteeing the prescribed estimation accuracy with limited communication resources. A hierarchical fusion estimator presented in Song et al. (2014) involves an optimal local estimator in the minimum variance sense and a fusion strategy combining local estimates with the previous fused estimate. In order to provide a satisfactory estimation precision with low computational burden, Zhang et al. (2016) present a sequential measurement fusion strategy for local estimators and a sequential covariance intersection fusion strategy for fusion estimation.

For the industrial IoT, many MTC devices are deployed to achieve the ubiquitous situation awareness in a coordinated way. The similar fog-cloud hierarchical architecture consisting of many sensors (MTC devices), several edge estimators (MTC APs), and one remote estimator (MTC gateway) shown in Fig. 1, where sensors are divided into clusters and each cluster includes a cluster head acting as the edge estimator.

System Control

In industrial IoT, the separation of control and actuation involves the data transmission of control commands over shared wireless

Resource Allocation in Industrial IoT, Fig. 1 Hierarchical network architecture for state estimation

Resource Allocation in Industrial IoT, Fig. 2 Network architecture for system control in industrial IoT

channels. In general, the more information the controller sends, the more precise actuation becomes, leading to that the control performance improves at the cost of more energy and spectrum resources. In the past decade, the communication-constrained control has been widely investigated in the area of networked control (Donkers et al. 2011; Cao et al. 2015; Gatsis et al. 2015; Al-Areqi et al. 2015). In order to guarantee the system stability and improve control performance, the control-scheduling strategy is adjusted based on system dynamics, while satisfying the resource constraint imposed by the communication network.

Besides designing the control-scheduling strategy based on system dynamics, another important issue is how to successfully complete the resource allocation for the scheduled subsystems over lossy wireless channels. However, in these aforementioned studies, the assumption about the perfect communication of control commands is over ideal. In practice, the harsh industrial wireless environments, such as electromagnetic interference, high temperature and humidity levels, vibrations, dirt, and dust, may result in the uncertain and stochastic wireless channels (Gungor and Hancke 2009; Lei et al. 2016; Doe 2004). How to achieve a reliable and efficient data transmission with poor channel conditions has attracted a lot of attention from both academia and industry. Traditional techniques to enhance the reliability of wireless

communications, such as retransmission and redundancy (Mahmood et al. 2015), focus on transmitting additional packets or bits to achieve the loss recovery. A price we need to pay, however, is the increasing time delay and energy consumption. Thus, they are not suitable for the delay-sensitive and energy-limited industrial IoT applications (Sadi and Ergen 2015). When the time diversity is not viable in the delay-sensitive scenario, exploiting the spatial diversity is a real choice to improve the transmission reliability for industrial automation systems (Swamy et al. 2017). Swamy et al. (2017) has proposed a wireless communication protocol that capitalizes on multiuser diversity and cooperative communication to achieve the ultra-reliability with a low-latency constraint.

In general, multiple independent subsystems share wireless channels. Each control subsystem consists of one sensor-actuator pair, whose feedback control commands are transmitted from the remote controller to actuators. In addition, the remote controller transmits many independent control signals to many independent actuators. As shown in Fig. 2, the dynamics of different subsystems are generally different, which makes the control inputs of different subsystems different. In this case, different actuators usually execute different control commands to stabilize their own subsystems. For control applications in industrial IoT with multiple subsystems, subsystems with different dynamic characteristics have distinct

impacts on guaranteeing the stability and reducing the overall control cost of whole system. To solve such problem, it is necessary to design an efficient resource allocation strategy to guarantee the system stability and reduce the overall cost. By taking the unreliable transmission imposed by the lossy wireless channels into account, the remote controller is in charge of jointly optimizing the control scheduling and the resource allocation, which is beneficial to guarantee the stability of each subsystem constrained by limited spectrum and energy resources.

Conclusion

The resource allocation strategy severely affects the data transmission reliability and the control system performance. Therefore, it is necessary to properly assign multidomain resources for industrial IoT to improve the control-communication performance.

Resource Allocation in NOMA-Assisted D2D Networks

Synonyms

Device-to-device (D2D) communication; Interference management; Non-orthogonal multiple access (NOMA); Resource management

Definition

Resource allocation in NOMA-assisted D2D networks is to assign the available resources including D2D communication modes, spectrum resources, and transmit power.

Historical Background

The fifth-generation (5G) network will possess an architecture of heterogeneous networks integrating with multiple advanced communication technologies to satisfy high performance requirements (Agiwal et al. 2016). Non-orthogonal multiple access (NOMA) technology is widely recognized as a key technology for 5G networks to support massive connectivity and high network capacity (Ding et al. 2017). The NOMA technology can utilize the non-orthogonal domain to enable that multiple users reuse the same orthogonal resource to transmit their signals, which effectively improves the spectrum utilization. The current NOMA technologies mainly include two

categories, which are based on the power domain and the code domain, respectively. Specifically, for the power domain NOMA, the signals of different users are transmitted on different power levels. Then, the successive interference cancellation (SIC) is utilized to decode the signals of the users by the difference on power domain (Islam et al. 2017). For code domain NOMA, several techniques have been proposed by the academia and industry, including sparse code multiple access (SCMA), pattern division multiple access, low-density spreading, and so on. By the code domain NOMA, the user is assigned with unique codeword or pattern to transmit the signal. At receiver, the multi-user joint detection is utilized to decode the signals of users according to the design of codebooks or pattern clusters, e.g., message passing algorithm for SCMA (Nikopour and Baligh 2013; Taherzadeh et al. 2014; Dai et al. 2017).

Device-to-device communication is one of the promising technologies to provide the proximity service for wireless devices, e.g., smartphones, connected vehicles, and drones (Asadi et al. 2014). Exploiting D2D communication, the nearby users can directly communicate with each other without the relay of base station (BS), which effectively improves the network capacity and energy efficiency. Different from other short-range communication techniques, D2D communications coexist with cellular networks and are managed by the cellular network. There are two D2D communication modes, which are the over-

lay mode and the underlay mode (Yu et al. 2014). In the overlay mode, D2D users dedicatedly utilize the network resource which is orthogonal with the cellular resources. Hence, beside the cellular resources, the dedicated resources should be required for D2D communication. In the underlay mode, D2D users share the same resource with cellular users to promote the resource utilization. However, the mutual interference between cellular users and D2D users will be caused, which degrades the performance of both cellular transmission and D2D transmission (Feng et al. 2013). Therefore, it is necessary to implement the efficient resource allocation for D2D communications and cellular users. Furthermore, it is significant to design the resource allocation and network scheduling for D2D in NOMA-enhanced cellular network, which is an important scenario in 5G networks. Figure 1 shows an example of NOMA-assisted cellular and D2D networks.

Since multiple cellular users transmit the signals via the same resource in NOMA system, the co-channel interference exists between the cellular users, which is different from traditional orthogonal multiple access (OMA) system (Yang et al. 2016; Ding et al. 2014; Di et al. 2016). Therefore, we should consider the impact of D2D communication on multiple users' NOMA transmission. For example, in power domain NOMA, the underlay D2D transmission can cause the interference to NOMA transmissions, which changes the co-channel interference and further influences the original execution of SIC

R

Resource Allocation in NOMA-Assisted D2D Networks, Fig. 1 D2D in NOMA uplink cellular network

decoding. The failure of SIC decoding leads to the series of failed user detection rather than only one user to degrade the reliability of NOMA system. Therefore, in NOMA-enhanced cellular networks, the mode selection and radio resource allocation for D2D communication is an important and challenging issue, which can acquire the advantages of NOMA and D2D on the spectrum efficiency and network connectivity (Pan et al. 2018; Liu et al. 2016).

Foundations

For NOMA-assisted D2D networks, the resource allocation mainly focuses on the mode selection of D2D transmission and resource management. The mode selection is to determine the resource sharing approach of D2D transmission in NOMA cellular users. Due to the non-orthogonal resource sharing between cellular users, the mode selection should consider the impact of the D2D transmission on NOMA transmissions to guarantee the efficiency of resource sharing between D2D transmission and NOMA cellular users. The radio resource management includes the subchannel/codebook assignment and power allocation, which aims to improve the spectrum efficiency of NOMA-assisted D2D networks.

Mode Selection for NOMA-Assisted D2D Communications

There are two typical D2D communications, the overlay mode and the underlay mode. The mode selection between the overlay mode and underlay mode has been widely studied by a number of literature (Lin et al. 2014; ElSawy et al. 2014; Ye and Zhang 2015). However, the D2D mode selection in NOMA system is a different issue and becomes more challenging. In power domain NOMA, if we select the underlay mode for the D2D transmission, the D2D transmission cannot break the NOMA transmissions of multiple cellular users on the same resource, which is different from that in OMA system where the D2D transmission only interfere with only one cellular user (Pan et al. 2018; Zhao et al. 2017). For SCMA-assisted D2D and cellular hybrid network, the

D2D mode selection depends on the mapping rules between the users and SCMA codebooks, which become more complicated than traditional OMA-based hybrid network (Zhai et al. 2017). In fact, the overlay mode and underlay mode are proposed based on the features of OMA system. Due to exploiting the code domain and power domain, the NOMA system has the potential to provide a new D2D mode to improve the efficiency of resource sharing between the cellular user and D2D pair. The NOMA-based D2D communication is promising and challenging issues for the future research works.

Resource Management for D2D Communications in NOMA System

For D2D communications, the radio resource management is of critical importance to guarantee the quality of service (QoS) of the network and satisfy the user requirements. Efficient resource management can restrain the interference, reduce energy consumption, and increase system rate. Due to the coexisting of D2D users and cellular users, the interference management is a challenging issue, which becomes more complicated in NOMA-enhanced D2D and cellular hybrid networks. In NOMA-enhanced D2D and cellular hybrid network, there are two types of the interference, which are the co-channel interference between NOMA users and the cross-tier interference between D2D users and cellular users. Therefore, how to design efficient resource allocation scheme is an important issue for interference management in this hybrid networks. The joint optimization of subchannel assignment and power allocation is a vital resource management method to alleviate the interference and improve the system capacity. For power domain NOMA, the joint subchannel and power allocation has been investigated by several works (Pan et al. 2018; Zhao et al. 2017). For code domain NOMA, the resource allocation is also studied by several papers (Zhai et al. 2017; Dai et al. 2016). The resource management issue for NOMA-assisted D2D networks is mainly formulated and solved by the optimization theory (Boyd and Vandenberghe 2004), matching game theory (Gu et al. 2015), and graph theory (West 2001).

Key Applications

Recently, the NOMA has been investigated in many 5G scenario to break through the bottleneck of the traditional OMA system, especially for ultra dense network and the scenario demanding the massive connectivity. Similarly, D2D communications are applied into emerging scenarios, such as the wireless caching, cooperative transmission, and connected vehicular networks (Qian et al. 2017; Di et al. 2017; Ding et al. 2018). Therefore, the resource allocation for D2D communications in NOMA-enhanced wireless communication system plays a vital rule for improving network capacity and user experience. We give several applications of the resource allocation in NOMA-assisted D2D networks as follows.

- **QoS-aware network capacity maximization:** One main application of resource allocation in NOMA-assisted D2D network is to maximize the network capacity while satisfying the QoS requirement of the users (Pan et al. 2018; Zhao et al. 2017). The QoS requirements have several aspects including the minimum rate, maximum transmission delay, and maximum energy consumption. However, the complicated interference between transmission links can not only severely degrade the network capacity but also destroy the original NOMA cellular transmissions. Thus, the efficient resource allocation should coordinate the interference to improve the network capacity while meeting the user requirements. The resource allocation problem usually can be formulated as an optimization problem.
- **Transmission delay minimization:** Due to the advantages on transmission efficiency, the NOMA technology is utilized to reduce the transmission delay. In the Internet of Things scenarios, the D2D communication enables the information transmission between the devices, such as the vehicle-to-vehicle communications and e-health sensing, where the transmission delay and link reliability are focused on. Thus, we should design the

appropriate resource allocation scheme for this kind of NOMA-enabled D2D networks to achieve low-latency and high-reliable communication. The NOMA for high-reliable and low-latency vehicular communications has been studied in Di et al. (2017). The performance of NOMA-enabled wireless caching is investigated in Ding et al. (2018).

Definitions

Resource allocation is the assignment of available resources including computing, storage, and networking resources to the customized services to achieve better QoS provisioning. In SDN/NFV-enabled 5G networks, heterogeneous resources are virtualized and allocated to different network services composed by ordered chains of virtual network functions (VNFs).

Historical Background

Traditionally, network infrastructure are managed and maintained by different network operators independently. In this business model, to deploy a network service for each network operator, the data traffic needs to flow through a certain fixed group of middleboxes, such as firewall, DNS (Domain Name System), and IDS (Intrusion Detection System), in a predetermined order (Li et al. 2018). The problem of choosing the set of required middleboxes and deciding the corresponding routing paths is called “middleboxes orchestration.” In an existing network, this task is manually executed through a “trial-and-error” approach, which is very costly and time-consuming. Furthermore, once placed, it is costly and impractical to change the location of a

middlebox according to the variations of network conditions.

In the context of SDN/NFV-enabled 5G networks, a network service can be formed with a set of chained virtual network functions (VNFs). Therefore, a network service is typically defined by the types of the VNFs chained, the processing order of the VNFs in the chain, and the embedding of the chain onto the network function virtualization infrastructure (NFVI). Figure 1 illustrates the transition from traditional network to SDN/NFV-enabled 5G network. Note that the function-specific middleboxes are replaced by commodity servers to host VNFs. A logically centralized SDN controller, which has a global view of the whole network, is used to manage and allocate the resources in the network. Through virtualizing network functions, new services can be accommodated by updating the software on the network servers instead of deploying new devices. In this way, the service provisioning cost can be reduced while the resource utilization can be improved. On the other hand, the use of SDN facilitates the realization of network openness and programmability. Despite the benefits brought by NFV and SDN, one of the main challenges in SDN/NFV-enabled 5G networks is, how to efficiently manage, allocate, and optimize the heterogeneous resources, including computing, storage, and networking resources, to the customized services for better QoS provisioning (Li et al. 2017).

Foundations

In SDN/NFV-enabled 5G networks, the resource allocation task (also referred to as network function virtualization resource allocation, NFV-RA) is implemented in three aspects (Herrera and Botero 2016), i.e., given the traffic metrics, QoS requirements, and resource constraints of the substrate network, we first need to compose a VNF chain to form a virtual network (VN) topology. Then virtual resources allocated to each element (VNF or virtual link) need to be optimized in order to minimize the provisioning cost and to satisfy the QoS requirements. This process is usually referred to as *VNF chain composition*. Next, we need to embed the virtual network (i.e., the VNF chain) onto the substrate network. During this stage, we need to assign the physical resources in an economical way to meet the resource demands of virtual nodes and links. This involves determining the locations of NFV nodes to host the VNFs and the routing from source to the destination. This process is referred to as *VNF chain embedding*. Finally, we need to schedule the VNFs for multiple services to minimize the service completion time and maximize the network performance. In other words, when multiple VNFs are embedded on the same NFV node, each of them should be assigned an optimal time slot. This process is referred to as *VNF scheduling* (Xie et al. 2016).

R

Resource Allocation in SDN/NFV-Enabled 5G Networks, Fig. 1 Global resource management and allocation via centralized SDN controller in core networks

- VNF chain composition: In the NFV environment, a network service request is an entity composed by a number of VNFs in a pre-determined order (Martini et al. 2015). Different from the existing network where network functions are run on dedicated hardware appliances on fixed locations, VNFs are softwares with much higher deployment flexibility, leading to increased complexity in composing the VNF chains. Therefore, it is crucial to investigate the chain composition process to produce VNF chains more efficiently and to allow the fast deployment of customized SDN/NFV-enabled network services (Ye et al. 2016).
- For a given network service request, the following information is typically known: (1) set of VNFs in the request and the dependencies between them; (2) fixed substrate nodes of initial and terminal points for the traffic flow; (3) initial data rate of the traffic flow; (4) the ratio of outgoing to incoming data rate of each VNF; and (5) the processing capacity demand per bandwidth unit of each VNF. There are many factors that increase the complexity and hardness of the VNF chain composition problem. First of all, the ordering of VNFs are flexible but has to respect to the dependencies between the VNFs. Different ordering of VNFs may result in different physical resources requirements (which is related to the embedding cost) for the resultant VNF chain. This flexibility increases the searching space of the optimal VNF chaining. Secondly, traffic splitting may be required in situations where the residual physical resources of a node (or a link) are not enough to support the network service. In such scenarios, some VNF has to be instantiated on multiple NFV-enabled nodes and the data traffic has to traverse through different VNF instances running on multiple nodes. This will further increase the hardness of the VNF chain composition problem. Thirdly, once the order of VNFs is determined, we need to determine the set of physical resources allocated to the VNFs and virtual links, to minimize the embedding cost while providing QoS-guaranteed services. Lastly, as the physical resources of the substrate network is limited, it is also important to take the substrate network condition, more specifically, the locations, residual capacities, and host abilities of substrate nodes into consideration in the VNF chaining process to improve the overall network performance. This will make it even harder to obtain the optimal solution to the VNF chain composition problem.
- VNF chain embedding: Once the VNF chain is composed via the chain composition process, the input to the second stage of NFV-RA is obtained. The VNF chain embedding process tries to place the VNFs on NFV nodes in the NFVI with multiple network service requests consideration. The VNFs should be consolidated in a way such that the physical resources are optimally allocated to the VNF chains with respect to a specific network operator's objective (e.g., maximizing the total revenue). The problem of embedding VNF chains onto the network function virtualization infrastructure is another challenging resource allocation task in the implementation of NFV.
- VNF chain embedding can be divided into two subproblems: virtual node mapping and virtual link mapping (Chowdhury et al. 2009). In VNF chain embedding, each substrate node can host a set of VNFs of different types. Since each VNF functions uniquely requires specific physical (computing, storage, or networking) resources, a VNF can only be assigned onto a substrate node that has the ability to host it. Furthermore, the VNF chain embedding stage needs to deal with dynamic networking condition changes and service description variations, which means: (1) with new services arriving and old services leaving the network, the existing VNF placement scheme may be modified to accommodate the newly coming service requests and improve resource utilization; (2) when the data rate entering an existing function chain changes, the orchestrator should notice that and trigger an adjustment algorithm to re-embed the corresponding VNF chain and reallocate the physical resources to achieve better overall network performance. Lastly, as the

intermediate stage of the NFV-RA problem, VNF chain embedding is closely related to the other two stages. It is of great importance to jointly study VNF chain composition and embedding, VNF chain embedding and VNF scheduling, and even the three stages together to obtain the optimal resource allocation solution for the NFV environment, though the problem complexity can increase seriously.

- VNF scheduling: The last stage of NFV-RA is the VNF scheduling process. Given the embedding results of VNF chains, this process tries to find a proper scheduling of VNFs' execution on each substrate node to minimize the "makespan" (the final execution time of the last VNF of the last executed network service). The results of a VNF scheduling process is closely related to the VNF chain embedding stage. The embedding process should aim to maximize the performance of the VNF scheduling stage. Therefore, it is desired to solve the VNF chain embedding and VNF-SCH problems in a coordinated way. Alternatively for simplicity, the two problems can also be solved independently where the results of VNF chain embedding are taken as the inputs to VNF scheduling (Qu et al. 2016). There are several technical challenges that need to be addressed when we consider VNF scheduling. Firstly, most of the existing proposals neglect the transmission delays of the links, how to obtain a feasible solution to the VNF scheduling problem involving the link delays remains a challenge. Moreover, currently, most existing studies focus on static scheduling algorithms in which the VNFs cannot migrate to other servers as network condition varies after performing the initial embedding and scheduling. The development of dynamic VNF scheduling algorithms remains an issue. Lastly, greedy and metaheuristic approaches exist in the literature to tackle the online VNF scheduling problem. How to formulate VNF scheduling based on mathematical optimization and solve it efficiently is also challenging.

Key Applications

It is possible and of great importance to integrate SDN and NFV in the same network to accelerate the shift toward "software-based" network services. NFV promotes the type of networking capabilities offered in service provider and cloud platforms and enables network services to be dynamically deployed among shared NFV nodes. SDN has been recognized as a key technology for the realization of a more efficient and flexible data center infrastructure. It is also a key driver in the development of edge computing and cloud computing. With the use of SDN, it becomes easier for the organizations to host applications on the most appropriate resources.

Resource allocation; UAV communication; UAV-aided wireless network

Definitions

Unmanned aerial vehicle (UAV)-aided wireless network (UWN) is designed to provide wireless network coverage to infrastructure-less or spectrum-scarce areas. Resource allocation in UWN is to assign communication, computing, or caching resources among UAVs and the connected terrestrial base stations (BSs) to improve the network performance or service quality of users.

Historical Background

Ubiquitous connectivity is demanded by future wireless networks to support massive users with heterogeneous service requirements. However, current terrestrial wireless networks have limited radio coverage in remote or post-disaster areas, and lacks the flexibility to be re-deployed according to the dynamic variations of terrestrial user traffic. To solve the coverage and flexibility

issues, UWN is proposed by some researchers in which UAV is integrated with the wireless communication technology (Mozaffari et al. 2018). The UWN can be formed in two types, i.e., the flying ad hoc networks (FANET) composed by swarms of UAVs and the UAV-assisted radio access networks (UA-RANs) where UAVs perform as the wireless coverage extension of terrestrial BS. Specifically, the FANET is mainly used to provide temporal wireless communication services for the infrastructure-less areas (Liu and Kato 2016); while the UA-RAN is considered to enable dynamic deployment capability for future RAN to ensure the QoS for the highly variable data traffic (Bor-Yaliniz and Yanikomeroglu 2016). The two types of UWN are shown in Fig. 1. Compared with those resource allocation schemes in terrestrial networks, the communication, computing, and caching resource allocations in UWN have to jointly consider the impacts of UAV's 3D dynamic movement, i.e., the UAV static deployment (Mozaffari et al. 2017) or the UAV trajectory design (Wu et al. 2018). Compared with traditional resource allocation schemes in terrestrial networks, the impacts of UAV's 3D dynamic movement, i.e., the UAV static deployment (Mozaffari et al. 2017) or the UAV trajectory design (Wu et al. 2018), should be considered when jointly allocating the communication, computing, and caching resources.

Foundations

Compared with terrestrial wireless networks, UWN has four advantages:

- **Line-of-sight (LoS) connection:** Constrained by the two-dimensional topology, terrestrial wireless links are obstructed by vehicles or buildings frequently. As a result, most messages are transmitted through non-line-of-sight (NLoS) wireless links which can seriously decrease the quality of service (QoS) of users. Contrarily, UAVs flying in the air

Resource Allocation in UAV-Aided Wireless Networks, Fig. 1 FANET and UA-RAN

have higher probability to connect ground users via LoS links, which facilitates highly reliable communications. This advantage is further enhanced by UAV’s capability of allowing 3D adjustments of their positions to avoid obstacles between DBSs and users.

- Dynamic deployment: Different from traditional BSs which are statically fixed on dedicated locations, UAV can be dynamically deployed according to the spatial and temporal changes of ground traffic, and be assigned to different users or controllers on demands Shi et al. (2018a).
- Fully-controlled mobility: Different from connected vehicles in VANET whose mobility is controlled by drivers or autonomous vehicles themselves, the hovering positions and flying trajectories of UAV are fully controlled by the corresponding controllers. This fully-controlled mobility feature enables the dynamic deployment feature of DBSs to assist ground infrastructures.
- Communication and computation integration: The UAV holds the capability to conduct both communication and computation tasks.

Considering the dynamic deployments of UAVs, joint communication and computation resource allocation mechanisms can be implemented to further improve the performance of terrestrial networks.

To further exploit the four advantages of UWN, resource allocation in UWN can be conducted in two steps: (1) determining the optimal static deployment or trajectory design results of multiple UAVs; then (2) allocating resource for each UAV and connected terrestrial infrastructures to maximize network performance. For the first step:

- UAV static deployment: The main design objective of UAV static deployment is to optimize multiple UAVs flying altitudes, horizontal positions, and/or spatial density to achieve the maximum user coverage ratio in a given area without violating dedicated constraints, such as interference, UAV-to-ground (U2G) pathloss thresholds, etc. According to the UAV static deployment results, multiple UAVs hover on optimized positions in 3D

space and serve their associated users who require additional communication resources. Since the distribution of terrestrial users and traffic are dynamically changing in both spatial and temporal domains, the UAVs have to be re-deployed periodically based on the changes. Typically the UAV static deployment problems are formulated as the NP-hard facility location problem or similar forms of it, which are usually solved through heuristic approaches (Shi et al. 2018a).

- UAV trajectory design: Compared with the static deployment, the UAV trajectory design allows multiple UAVs fly over their associated users periodically following the designed trajectories. There are two motivations to design the trajectory of UAVs: First, for some scenarios, the number of UAVs is inadequate to cover all users through the static deployment approach. Second, the static deployment inherently lacks the user fairness guarantee. Particularly, the users located at the edge of the UAV's radio coverage can suffer from severe pathloss compared with users located at the center of the UAV radio coverage. To promote the user fairness, each UAV can periodically fly over its associated users and provide communication servers for the specific user within its scheduled interval during which the minimal UAV-to-user (U2U) pathloss can be achieved. UAV trajectory design aims to design optimal trajectories and the scheduling results for multiple UAVs to maximize network QoS without violating given constraints. UAV trajectory design problems are typically formulated as unsolvable mixed integer (U2U scheduling) nonconvex (UAV trajectory) problems, which can be solved by some simplification or iterative optimization methods, such as coordinate descent (Wu et al. 2018).

Given the static deployment or trajectory design results, the resource allocation in UWN can be categorized in two types according to the

scenarios, i.e., resource allocation in FANET and resource allocation in UA-RAN.

- Resource allocation in FANET: Resource allocation in FANET mainly focuses on how to distribute resources or tasks among the swarm of UAVs to maximize the QoS of users who access the FANET through those UAVs. Classic resource allocation schemes in traditional ad hoc networks can be implement in FANET by involving some specific features of UAVs, i.e., U2G and inter-UAV channel models (Al-Hourani et al. 2014; Dabiri et al. early access, 2018), inter-UAV interference, inter-UAV cooperation, limited CPU and battery capacities of single UAV, etc. Specifically, the resource allocation as well as the deployment and trajectory design of UAVs in FANET are usually joint optimized to maximize the user QoS gains.
- Resource allocation in UA-RAN: For UA-RAN, since UAVs are used to relay user-to-BS (U2B) communications, the resource allocation between UAVs and the corresponding terrestrial BSs are more essential than the inter-UAV resource allocation. The objective of resource allocation in UA-RAN is to optimize the resource allocation among UAVs and the terrestrial RAN to maximize the QoS of UA-RAN users without violating the QoS of terrestrial RAN users. Despite the U2G channel model and inter-UAV interference, the U2B interference and U2B link quality constraints should also be considered in the resource allocation. UA-RAN has a similar network architecture to the Cloud-RAN (C-RAN) by regarding the UAV as the “flying remote radio head (RRH).” Therefore, the RAN slicing and edge computing techniques, which are widely used in C-RAN, can be implemented in UA-RAN to promote the resource allocation. As an emerging research topic, most existing works of UA-RAN resource allocation investigate the UAV-aided caching schemes (Chen et al. 2017).

Key Applications

UWN is mainly used to extend the wireless network service to uncovered areas (remote or post-disaster regions), and provide additional communication resources for spectrum-scarce areas in terrestrial RAN's coverage (congested road/stadium or radio coverage holes) (Shi et al. 2018b). Integrated with the terrestrial networks, UWN enables the flexibility to re-deploy the access network based on the dynamic changes of users in both spatial and temporal domains. Through appropriate resource allocation, UWN can enable QoS-guaranteed ubiquitous connectivity in future wireless networks.

Resource Management in Macrocell—Small Cell Systems and D2D-Assisted Cellular Systems

Yao-Liang Chung

Department of Communications, Navigation and Control Engineering, National Taiwan Ocean University, Keelung, Taiwan

Synonyms

Synonym 1. Macrocell—small cell systems; Heterogeneous cellular networks

Synonym 2. Device-to-device (D2D)-assisted cellular systems; D2D communication in cellular systems

Definitions

Definition 1 (Macrocell—Small Cell System).

A two-layer cellular network architecture in which the area covered by a macrocell base station (MBS) has multiple small cell base stations (SBSs) deployed within it (i.e., the areas covered by the SBSs are incorporated into the larger overall MBS coverage area). The term “heterogeneous cellular networks” is also used to refer to such concurrent operation of MBSs and SBSs.

Definition 2 (Device-to-device (D2D)-Assisted Cellular System).

A cellular network architecture that utilizes so-called D2D communication, that is, communication in which data can be sent directly (i.e., without first being sent to a base station (BS)) by each device to its destination device, thus allowing for the replacement of the cellular mode (through both uplinking and downlinking) for transmissions sent over short distances. Such a network architecture is also referred to as “D2D communication in a cellular system.”

Introduction

The study of cellular networks, which are an important type of wireless network, covers not just technological dimensions but also social and economic dimensions. Since the start of the transition from second- to third-generation cellular networks, communication standards have been regulated under the authority of the Third Generation Partnership Project (3GPP), an international collaboration among all the relevant companies and organizations. In a cellular network, base stations (BSs) play an important role as they enable devices connected to the system (BS) to communicate with each other. In first-, second-, and third-generation cellular networks, the radio access network (RAN) side can only utilize macrocell base stations (MBSs) to provide network services to their users. However, the rapid growth in the number of mobile phone users, increasing shipment volumes of smart handheld devices, and emerging application services have aggravated the problems associated with the surge in global mobile data flow (Cisco Visual Networking Index: Global Mobile Data Traffic Forecast Update 2016) and the imbalance between supply and demand. Telecom operators can no longer rely on a single technology (i.e., MBSs) to handle these problems. Furthermore, users seeking to operate devices indoors, at macrocell edges, or in certain locations such as caves, basements, elevators, etc. will occasionally encounter poor signal conditions or even signal dead zones (i.e., areas in which they are not able to get a signal from an MBS). Both of the aforementioned facts have together led to the development of heterogeneous access technologies (e.g., small cell base stations (SBSs) and device-to-device (D2D) communication) for flow offloading and coverage expansion in local area networks. Fourth-generation cellular networks went a step further by integrating a variety of heterogeneous access technologies (including Wi-Fi, SBSs, and D2D) to raise overall network performance. These technologies focused on improving factors such as spectral efficiency, energy efficiency,

and network coverage, so as to create a good mobile network usage environment for users. Going forward, fifth- and later-generation cellular networks will be shifting toward the use of multi-network heterogeneous network architectures that are even more advanced and efficient (Gupta and Jha 2015).

It is worth noting that SBS and D2D technologies, as well as the application prospects that they offer, are gaining widespread attention. These two technologies have opened up new opportunities with respect to local area network layouts for telecom operators and businesses dealing with equipment, chips, and software, and these businesses have made the two technologies the focal points of their research on fifth-generation cellular networks. However, regardless of the ways in which heterogeneous networks are further developed and deployed, efficient resource management (which covers key aspects including time, frequency, space, and power) still remains an important means and step in determining if a system's performance can meet its various objectives and demands. This entry will provide an introduction to macrocell—small cell systems and D2D-assisted cellular systems, which are created through the application of SBS and D2D technologies to macrocell networks. A comprehensive and up-to-date survey on resource management for such systems will also be given, so as to facilitate a discussion of potential commercial applications and future challenges.

Resource Management in Macrocell—Small Cell Systems

Background

SBS technologies have become a part of the discussion on standardization since 3GPP Release 8, and the key points of this discussion have included potential issues such as interference issues among SBSs, interference between MBSs and SBSs, and SBS deployment optimization in user-intensive areas. In comparison to MBSs, SBSs are access nodes that are lower in cost and use less energy but also have smaller coverage ranges (Small Cell Forum 2017). Because the

different types of small cells differ in terms of average transmission power and cell size, they are frequently classified into various subcategories including microcells, picocells, and femtocells, with various scholars having noted that investigations aimed at moving toward the use of smaller and smaller cells should constitute a major thread of future research (Fehske et al. 2014).

SBSs were originally developed to address poor indoor signals and macrocell edge signals, as well as signal dead zones. But with the emergence of fourth-generation cellular network architectures, which differ greatly from the ones used by previous generations, SBSs have become a deployment focus alongside MBSs. Moreover, the rapid growth of mobile data services has led to SBSs being utilized to offload mobile network flows and provide additional value-added services. In order to reduce operating costs and facilitate the installation of SBSs by users, telecom operators also require SBSs to be able to form self-organizing networks, such that they can perform self-configuration and optimization effectively. It is expected that, so long as the interferences among SBSs and between MBSs and SBSs can be sufficiently controlled, the communication quality for all application services will be considerably enhanced by the efficient deployment of SBSs within the coverage areas covered by MBSs.

Literature Survey

It should be noted, first, that a considerable amount of the existing research regarding the management of cellular network resources has considered only the involvement of MBSs in such networks, with a large number of studies having provided comprehensive investigations of how to improve system performance via the unique contributions of various approaches. For example, an efficient cross-layer packet scheduling and resource management scheme was proposed as a means of maximizing system capacity by Jeong et al. (2006), while fast algorithms aimed at computing the optimal allocation of resources for overall system utility maximization were proposed by Madan et al.

(2010). In still another approach, Rodrigues and Casadevall (2011) adopted two viewpoints in studying the trade-offs made between user fairness and resource utilization, whereas studies by Ng et al. were dedicated to investigating optimal resource allocation to ensure energy-efficient transmission in the context of both single-cell environments (Ng et al. 2012a) and multicell environments (Ng et al. 2012b). In a subsequent study, Ng et al. explored the effects of utilizing another type of MBS for data transmissions, specifically, an MBS that harvests hybrid energy (Ng et al. 2013). Meanwhile, due to ongoing advances in cellular technologies, it is now possible to simultaneously use more than one component carrier (CC) within a BS for transmissions. As such, a number of recent studies have consisted of investigations of systems involving MBSs that simultaneously utilize multiple CCs. For example, a study by Chung (2015a) proposed a rate-and-power control transmission scheme aimed at minimizing the amount of energy consumed by the transceivers of an MBS making use of two CCs at once while still ensuring that users would receive the required service quality and fairness. In a subsequent paper (Chung 2015b), the same author considered the same system in order to construct a framework that was then used to comprehensively examine potential means of maximizing transmission efficiency through both the maximization of system capacity and the minimization of the total amount of energy consumed. Chung followed that study by yet another in which he proposed a more flexible scheme aimed at both efficiently minimizing the total power consumed by the transceivers of an MBS when said MBS is simultaneously making use of two or more CCs and ensuring that the necessary service quality and fairness are still provided to users (Chung 2016a). The author then followed that study by still another proposing an efficient packet scheduling algorithm that could be used to increase transmission efficiency when both real-time traffic and non-real-time traffic are being transmitted (Chung 2016b).

Next, it is important to note that when multiple SBSs and MBSs are both present and used simultaneously in a given system, a range of complex resource management issues are consequently created. As such, various investigations focusing their attention on these issues have also been conducted. For example, members of the aforementioned 3GPP organization have conducted a range of discussions regarding potential approaches to minimizing the power consumed by evolved universal terrestrial radio access networks (3GPP TR. 36.927 V10.1.0 2011). Relatedly, a scheme proposed by Claussen et al. (2010) would utilize the detection of user activity to enhance energy efficiency, while a study conducted by Wang and Shen (2010) investigated the energy efficiency of individual cells (as measured in bits per Joule) as well as the energy efficiency of specific coverage areas (as measured in energy efficiency per unit area). The following year, 2011, a study was conducted by Auer et al. (2011) in which the different levels of energy used by different types of BSs were quantified, while a subsequent study by Aleksic et al. (2013) proposed a hybrid model to be used for assessing the energy efficiency of converged wireless/optical access networks. In 2015, 2 years after the publication of the study by Aleksic et al., Huang et al. (2015) proposed both distributed and centralized optimization methods aimed at addressing problems encountered in the optimization of small cell cluster coverage, while in 2016, the possibility of imposing quality-of-service requirements and interference mitigation was investigated by Wang et al. as a potential means of enhancing transmission efficiency (Wang et al. 2016). Meanwhile, a number of transmission algorithms aimed at ensuring that data rate needs would be met even under various SBS deployment strategies and even while minimizing the total power consumed by the transceivers of all the BSs were proposed by Chung (2015c, 2017a). In addition, a 2014 study by Mekikis et al. (2014) proposed a method for determining the lowest cost of network deployment with random deployment, while in a still more recent study, a continuous-time Markov chain model that would allow the survivability

of networks subjected to extensive failures (such as failures stemming from natural disasters and security attacks, as well as common mode software and hardware failures) to be quantified was proposed by Xie et al. (2017). Meanwhile, systems involving the simultaneous activity of multiple mobile network operators have been the focus of other recent studies. For example, Antonopoulos et al. (2015) proposed a framework for providing enhanced throughput and energy efficiency in such systems via intra-operator spectrum sharing, while Bousia et al. proposed an auction-based switching off and offloading algorithm that could allow energy conservation and cost reductions by encouraging mobile network operators to switch off any redundant MBSs and offload their traffic (Bousia et al. 2016). Relatedly, a study conducted by Oikonomakou et al. (2017) investigated the energy and cost efficiency of a network effectively comprised of the cooperative actions of multiple mobile network operators. More recently still, other studies have given close attention to the problem of the signal dead zones that can sometimes be found in such heterogeneous cellular networks. For example, Chung (2017b) introduced a coverage algorithm aimed at providing the greatest possible decrease in the total power utilized by all of the transceivers of the BSs in a system while at the same time ensuring that comprehensive wireless signal coverage would be provided to users under a variety of scenarios; however, the algorithm's lone disadvantage was that it was not always able to fulfill the transmission rate requirements of users. Chung (2017c) then proposed a modified coverage algorithm to mitigate this disadvantage and ensure that the respective transmission rate requirements of all users can be met.

Commercial Applications

Currently, SBSs are primarily used to strengthen indoor signals and prevent signal dead zones, and relevant businesses are also hoping to utilize SBSs to operate value-added application services in specific regions. By being integrated with application-end equipment or devices, SBSs can

then be utilized in smart grids (Bu and Yu 2014), smart homes (Khan et al. 2015), and smart cities (Zhou et al. 2016), thus allowing for economic benefits to be generated.

Challenges

The deployment of SBSs in a high-density manner is viewed as one particularly promising approach to addressing the increasing demand of high capacity for next-generation cellular networks, with this approach being expected to be studied extensively in future research. However, one key point to address would be the various issues that arise from such deployments, which include signal interference, frequency band use, deployment strategies, backhaul/fronthaul high traffic load designs, and operation management.

Resource Management in D2D-Assisted Cellular Systems

Background

As for D2D technologies, they became a part of the discussion on standardization in 3GPP Release 12, and the key points of this discussion have included potential issues such as proximity-based services, device search mechanisms, resource management, interference control, converged interconnection, group communication, and security and privacy. In fact, long before the introduction of 3GPP Release 12, the development of D2D technologies (such as Bluetooth) had been ongoing for some time, yet there had been a lack of results with respect to the development of key applications and, correspondingly, the commercial adoption of such technologies. However, in recent years, the emergence of a multitude of smart mobile devices and mobile services and applications has resulted in a surge in mobile data flow, the growth of community networks, and the increasing application of the Internet of Things (IoT), all of which have attracted renewed industry and academic interest in D2D technologies.

In traditional cellular networks, the RAN side can only establish communication links with the support of MBSs. But with the application of

D2D technologies, mobile devices within a certain range can perform direct data transfers without the support of MBSs, and at this point, every device in the network will possess the ability to transmit, receive, and relay data. Through effective resource management, D2D technologies can provide advantages such as offloading for MBSs, the reduction of transmission delays, the raising of data rates, spectral efficiency, energy efficiency, and the expansion of network coverage.

Literature Survey

D2D communication can be divided into four categories according to the different kinds of frequency bands (specifically, licensed bands and unlicensed bands) that past studies have used for D2D communication: (1) D2D communication for which only licensed bands are used (such as that described in Asadi et al. (2014a) and Doppler et al. (2009); Janis et al. (2009); Zulhasnine et al. (2010); Feng et al. (2013); Wen et al. (2013); Wang et al. (2012); Akkarajitsakul et al. (2012); Doppler et al. (2010); Chung and Lin (2014); Gao et al. (2017); Giatsoglou et al. (2017); Chen et al. (2017); Datsika et al. (2016)), (2) D2D communication for which only unlicensed bands are used (such as that described in Asadi et al. (2014a) and Asadi and Mancuso (2013); Golrezaei et al. (2014); Dimitriou et al. (2013); Mastorakis et al. (2013); Bourdena et al. (2014); Antonopoulos et al. (2014); Datsika et al. (2016, 2017)), (3) D2D communication for which either licensed or unlicensed bands are used in a selective manner (such as that described in Asadi et al. (2014b, 2015)), and (4) D2D communication for which both licensed and unlicensed bands are used simultaneously (such as that described in Chung (2017d, e)). With regard to the first two categories, Asadi et al. (2014a) reported a D2D communication survey and overview that showed that D2D connections can effectively mitigate the transmission delays and traffic loads faced by MBSs, with those D2D connections also resulting at the same time in enhanced system throughput and better energy usage efficiency (effects which in turn result in decreases in the amount of overall power utilized by a network). Relatedly,

the amount of clearly established research results regarding the first two categories is greater than the amount of such research results regarding the third and fourth categories; as such, there is substantially more research progress that can still be accomplished with respect to the latter two categories.

According to a study by Doppler et al. (2009), one way of potentially reducing the effects of interference to a substantial degree would consist of imposing limitations on the distances of transmissions and the transmission power consumed by D2D pairs. Meanwhile, resource allocation schemes that would potentially cause interference levels to be reduced have also been proposed by Janis et al. (2009) and Zulhasnine et al. (2010), although one limitation of both of those schemes is that they can be employed only for D2D pairs themselves. More recently, still other potentially beneficial resource allocation schemes have been presented by other relevant studies, including those by Feng et al. (2013) and Wen et al. (2013). That said, while a variety of D2D communication studies have been produced, it should be noted that system throughput was the primary focus of much of that research. However, given that mobile devices typically have a limited amount of battery energy available to them, and because energy efficiency is increasingly seen as a key consideration in the design of both mobile devices and network schemes, the efficient use of power and various related subjects has recently been given greater research attention. For example, in a study concerning uniformly distributed D2D networks, Wang et al. (2012) suggested the use of reverse iterative combinatorial auction games as one potential means of providing energy-efficient resource allocation, while in the previously mentioned study conducted by Wen et al. (2013), the question of how to improve D2D cluster energy efficiency was explored. Still other studies have considered the opportunistic switching of communication modes as another potential method for addressing the same issue (Akkarajitsakul et al. 2012; Doppler et al. 2010), while more recently, Chung and Lin (2014)

introduced a transmission algorithm intended to reduce overall power consumption while also making sure that all users would still have their transmission rate requirements met. Meanwhile, Gao et al. (2017) conducted an analysis of how energy efficiency changes in D2D-assisted cellular networks alter spectrum efficiency, and vice versa, while new techniques for potentially improving system performance in D2D communication have been explored in a number of other recent studies. For example, Giatoglou et al. (2017) proposed a device caching approach intended to facilitate the exchange of content via millimeter-wave D2D communication, while an approach based on the use of D2D communications to leverage any substantial crowd of devices located at a network's edge as a means of providing energy-efficient collaborative task execution was proposed by Chen et al. (2017). It should be reiterated, incidentally, that the D2D-related studies just described all considered the issue of transmission over licensed bands.

That said, the subject of D2D communication over unlicensed bands has recently become a subject of greater interest among researchers due to the simple fact that the majority of newer mobile devices use at least two wireless interfaces when operating. For example, a protocol focusing on the topic of implementation was proposed in a paper by Asadi and Mancuso (2013), while the use of localized D2D communications as a means of increasing the throughput of video files transmitted via cellular communication systems was suggested by Golrezaei et al. (2014). The year before, in 2013, Dimitriou et al. (2013) published a study in which a device-focused methodology was used to analyze the design, development, and experimental evaluation of a scheme for heterogeneous wireless networks based on the use of delay-bounded energy-conscious bandwidth allocation. In the same year, Mastorakis et al. (2013) published a study proposing an energy-efficient routing scheme intended to enhance the energy efficiency and data transmission reliability communication devices possessing heterogeneous radio spectrum availability. The following year, Bourdena et

al. (2014) expanded upon that earlier study by Mastorakis et al. (2013). It should be noted, meanwhile, that whenever multiple devices attempt to engage in D2D communications over unlicensed bands, channel access issues will inevitably be raised, particularly in those situations wherein all the devices involved have the same aim with regard to content dissemination. The need to identify effective schemes for providing medium access control (MAC) is underscored by the occurrence of such situations, and in fact, the relevant issues have been explored and addressed in several recent studies. For example, Antonopoulos et al. (2014) proposed a pair of game theoretic MAC schemes aimed at providing rapid and energy-efficient content dissemination, while Datsika et al. (2017) proposed a network coding-based MAC approach for data exchange via D2D transmissions. In a slightly earlier study, meanwhile, an overview of D2D communication and MAC design challenges involving energy consumption issues and social behaviors was also provided by Datsika et al. (2016).

One key issue impacting the use of either licensed bands only or unlicensed bands only to complete D2D transmissions is that both approaches provide differing advantages and disadvantages with respect to the resulting implementation complexity, spectral efficiency, and interference control (for more details, see Asadi et al. (2014a)). Therefore, the overall performance of the system in question will suffer if just one or the other approach is used exclusively. With that in mind, the selective use of both licensed and unlicensed bands was examined by Asadi et al. in two of their recent papers (Asadi et al. 2014b, 2015). Specifically, they suggested a heuristic solution called "Floating Band D2D" as one potential means of making better use of the potential benefits of utilizing both licensed and unlicensed bands. That is, their proposed solution was intended to guide a network such that either licensed or unlicensed bands would be used appropriately for a given D2D data transmission. More recently, Chung (2017d) published a study investigating the full and simultaneous use of both licensed

and unlicensed bands for D2D communication wherein the goal of providing users with more optimized average transmission rates was effectively accomplished. In yet another study, meanwhile, the same author (Chung 2017e) proposed a transmission algorithm based on the deployment of novel system configurations as a means of providing enhanced utility in using both the licensed and unlicensed bands; the results indicated that the proposed algorithm could not only provide all connected users with acceptable transmission rates but that it could also improve system performance in terms of both connection efficiency and energy efficiency to a significant degree.

Commercial Applications

In cellular systems, the use of D2D communication is directly and practically relevant to a wide variety of information and communication technology applications, including the IoT (Xu et al. 2014), Internet of Vehicles (Ferreira et al. 2014), wireless sensor networks (Marchenko et al. 2014), and wearable devices/sensors for healthcare (Lin et al. 2016). Some potential examples are discussed in the aforementioned work (Chung 2017d) by Chung. The application of D2D communication in the abovementioned fields can lead to the development of application services that carry high social and economic value.

Challenges

At present, the subject of efficient D2D-assisted transmission involving simultaneous and completely flexible use of both licensed and unlicensed bands in cellular systems has yet to be comprehensively researched. Given the substantial relevance of this topic to next-generation cellular networks, further research is certainly required with regard to the question of how both power and radio resources can be efficiently employed in D2D-assisted cellular systems utilizing both licensed and unlicensed bands. Relatedly, research regarding the integration of SBS and D2D technologies in a single system as means of further raising network performance is also gaining increasing momentum.

Resource Scheduling in Virtualized Wireless Networks

Xianfu Chen

Oulu, Finland

Synonyms

Elastic wireless resource management; Wireless resource virtualization

Definition

Resource scheduling refers to the sequences of decision-makings from an entity ensure the accomplishment of tasks arriving to the network based on the resource availabilities. In virtualized wireless networks, the resource can be not only network slices with specifically designed functionalities but isolated frequency spectrum.

History

The proliferation of mobile devices and data-intensive applications has caused a significant demand of wireless network services to grow at a rapid rate. The global mobile data traffic is estimated to increase eightfold between 2015 and 2020 (Cisco 2016). To keep pace with the enormous demands, the current spectrum efficiency has to be extended by at least a factor of 10. Network densification has been considered as the dominant theme towards future wireless networking (Andrews et al. 2012). That is, the

cells tend to be smaller, which indicates that the traditional border among different radio access technologies will disappear. On one hand, an advanced dense network infrastructure can certainly achieve seamless mobility, much higher network capacity and spectrum and energy efficiency due to shorter transmission range and less number of mobile users per cell site. On the other hand, the mobile data traffic evolves from being voice-dominated to being data-dominated. The revenue per unit-data for wireless network operators is declining at an unhealthy rate, whereas the costs are increasing considerably with the heavy budgetary burden of upgrading network infrastructures. All these trends are pushing the wireless network operators to find a better way to provide wireless services.

Due to the potential performance gains and the inherent cost-saving benefits by utilizing economics of scale and avoiding duplicated investment on the network infrastructure, radio access network sharing among the wireless network operators has attracted extensive attention and emerges as a promising mechanism to control both the capital expenditure and the operational expenditure (Liang and Yu 2015). More specifically, if a wireless service subscriber can freely connect to a base station of the wireless network operators and the base stations of one wireless network operator can reuse the spectrum of other wireless network operators, the network capacity can be significantly enhanced to accommodate more traffic generated from the subscribers. The worldwide combined capital expenditure and operational expenditure savings can be up to \$60 billion through radio access network sharing over a period of 5 years (Cellular News 2009).

However, the radio access network sharing activities are mostly based on long-term business agreements between the wireless network operators, and most existing radio access network sharing solutions have the drawbacks of orchestrating both data and control planes among the wireless network operators, customizing wireless services, and capability of adapting to dynamic network statistics in real world. Network virtualization facilitates radio access

network sharing, with which the traditional single ownerships of network infrastructure and spectrum resources can be separated from the wireless services. Consequently, the same physical network infrastructure is able to host multiple wireless service providers. The radio access in the virtualized wireless networks can be coordinated by a software-defined networking framework (Gudipati et al. 2013). Software-defined networking simplifies network management by decoupling the control plane from the data plane and is a natural platform for realizing network virtualization in radio access networks.

The recent advances in software-defined networking, cloud computing, as well as edge computing (Satyanarayanan 2017) provide technical enablers for a software-defined wireless network. The origin of the software-defined networking concept can be traced back to the 1990s. The success of software-defined networking comes from the systematic abstraction of complex networking problems in the Internet, which turns distributed networking problems into a logically centralized one. Software-defined networking gives rise to fundamental new thinking on the design of wireless networks. The development of a software-defined wireless network is highly connected to cloud computing which makes large-scale logical centralized control solutions feasible. Yet the traditional cloud computing architecture may have a problem in satisfying the strict latency requirements lying in control plane functioning. It is hence reasonable to move the logical centralized control close to the edge in wireless networks. Edge computing could fill this gap for a better architecture design of the software-defined wireless networks. Edge computing is a variant of the cloud computing concept but uses the computation resources and storages at the edge of a wireless network for a sustainable amount of communication, storage, control, and configuration. In a wireless network, edge computing can be utilized for the control and joint signal processing at the radio access network to serve densely deployed cells, while cloud computing can be used in core networks for packet processing and forwarding. The integration of edge

computing and cloud computing brings an end-to-end software-defined solution for the wireless networks.

Foundations

The decoupling of the control and data planes in a software-defined wireless network makes it a must to take into account different timescales in the scheduling of wireless radio resource. Wireless resource needs to carefully be split locally or remotely in order to match the new network architecture. The radio access network sharing among the wireless service providers add another level of challenges to wireless resource scheduling. The radio access network slicing is not simply the spectrum slicing but means the wireless resource isolation. Large-scale learning is an enabling technology that allows the wireless service providers to dig out the subscriber- and the service-level awareness in traffic over the widespread wireless networks and is a promising facilitator of real-time conversations between the wireless service providers and the virtualized wireless networks to influence the quality-of-service as well as the quality-of-experience of service subscribers, adapting to the network dynamics and the service usage.

The problem of wireless resource scheduling in a virtualized radio access network involving multiple wireless service providers is in general formulated as a multi-agent Markov decision process. In a large-scale multi-agent network setting, having complete environmental information over the time horizon is extremely challenging from the perspective of a wireless service provider. Alternatively, a wireless service provider makes partial observations of the environment, from which the abstract environmental information can be explored. Following this logic, we are able to implement the large-scale learning for wireless resource scheduling, which is then simplified to a series of independent single-agent small-scale learning.

Robust Games for Power Control in Multi-tier Cellular Networks

Kun Zhu², Ran Wang^{1,2,3}, and Xiangping Zhai²

¹College of Intelligence and Computing, Tianjin University, Tianjin, China

²Nanjing University of Aeronautics and Astronautics, Nanjing, China

³Department of Information and Communication Engineering, Tongji University, Shanghai, China

Introduction

Future wireless networks (e.g., 5G) are expected to be highly heterogeneous composed of macro-cells and a large number of small cells. However, the spectrum-wide cross-tier and co-tier interferences could severely limit the system performance. Accordingly, interference mitigation is of vital importance for which subchannel assignment and power control-based resource allocation have been shown to be a feasible solution for OFDMA-based heterogeneous wireless networks (HetNets).

Centralized resource allocation schemes requiring coordination among all BSs may not be practical in HetNets due to the large amount of small-cell base stations (SBSs) deployed, privacy protection by the owners, and security issues. Accordingly, a noncooperative setting is preferred where each BS is of self-interest and performs resource allocation independently and distributively aiming to maximize its own capacity. Also, a hierarchical structure of the competition among the macrocell base stations (MBSs) and SBSs is considered where the MBSs are assumed to have privileges over SBSs in making decisions, and the mathematical modeling fits naturally into the framework of a Stackelberg game.

Due to the dynamic and random nature of wireless environment and limited amount of coordination in HetNets, information uncer-

tainties naturally appear, and the assumption of perfect information may not be practical. Accordingly, when applying perfect information-based resource allocation schemes in a practical system with parameter uncertainties, possible performance degradation could be experienced. For example, interference constraints are usually imposed to protect high-priority users. However, these interference constraints could be violated due to the uncertainty in channel state information (CSI) in a system using a perfect information-based scheme. Therefore, a robust design of resource allocation is required which takes the imperfect information into account.

To explicitly model the parameter uncertainty, the actual value of the parameter is usually represented by the sum of an estimated nominal value and a perturbation term which is also regarded as the uncertainty part. Similar to that in optimization theory, two approaches are used in game theory literature to deal with the information uncertainties: a Bayesian approach considering average payoff optimization which leads to the development of Bayesian games and a worst-case approach based on robust optimization (Bental and Nemirovski 1998) for worst-case payoff optimization which leads to the development of robust games (Aghassi and Bertsimas 2006).

The Bayesian approach considers the uncertainty term as a random variable the probability distribution of which is assumed to be known, and the performance is guaranteed on an average basis. For the cases where the probability distribution is not available, the distribution-free worst-case approach is a better option which only requires information about the bound of uncertain parameters. Specifically, with the worst-case approach, the uncertainty term is assumed to be bounded within an uncertainty region, and certain level of performance can be guaranteed for every realization in the uncertainty set which can prevent undesirable performance fluctuations.

In this chapter, the uncertainty in CSI of interfering channels is considered following the worst-case approach. Specifically, the downlink power control problem in a two-tier HetNet with

imperfect CSI is formulated as a distribution-free multi-leader multi-follower robust Stackelberg game (RSG), where the MBSs are considered to be the leaders while the SBSs are the followers. The RSG is composed of a leader sub-game and a follower sub-game and accordingly can be expressed as an equilibrium program with equilibrium constraints (EPEC). Robust Stackelberg equilibrium (RSE) composed of a robust Nash equilibrium (RNE) for the follower sub-game, and a RNE for the leader sub-game is considered to be the solution of the RSG (Zhu et al. 2014).

System Model and Game Formulation

System Model

We consider downlink transmissions in an OFDMA-based two-tier cellular network consisting of a set $\mathcal{M} = \{1, 2, \dots, M\}$ of macrocells and a set $\mathcal{K} = \{1, 2, \dots, K\}$ of small cells sharing the same set $\mathcal{N} = \{1, 2, \dots, N\}$ of

orthogonal subchannels. Also, we assume that only one user is served by each MBS/SBS in each subchannel. Denote by $g_{lm}(n)$ the co-tier channel power gain between the MBS l and the user of MBS m on subchannel n . The cross-tier channel power gain between the MBS m and user of SBS k on subchannel n is denoted by $h_{mk}(n)$. Similarly, we can define the co-tier channel power gain between SBSs as $g_{jk}(n)$ and the cross-tier channel power gain between SBS k and user of MBS m as $h_{km}(n)$.

Imperfect CSI is considered which brings uncertainty into the system. Specifically, the actual value of the channel gain is expressed as the sum of an estimated nominal value and an uncertainty term as

$$g_{lm}(n) = \bar{g}_{lm}(n) + \Delta g_{lm}(n), \quad (1)$$

where $\bar{g}_{lm}(n)$ is the nominal value and $\Delta g_{lm}(n)$ is the uncertainty term. In this chapter, ellipsoidal uncertainty model is used due to its analytical tractability. Specifically, the channel uncertainty is described by

$$g_{lm}(n) = \{\bar{g}_{lm}(n) + \Delta g_{lm}(n) : \|\Delta g_{lm}(n)\|_{\mathbf{w}_{lm}(n)} \leq \epsilon_m(n)\},$$

$$= \left\{ \bar{g}_{lm}(n) + \Delta g_{lm}(n) : \sum_{l \neq m} |\Delta g_{lm}(n)|^2 w_{lm}(n) \leq \epsilon_m^2(n) \right\},$$

where $\|\cdot\|$ denotes the Euclidean norm of a vector and $\mathbf{w}_{lm}(n)$ is a vector of positive weights. Similarly, the uncertainty models for $g_{jk}(n)$, $h_{mk}(n)$, and $h_{km}(n)$ can be obtained.

The transmit powers of MBS m and SBS k are denoted by $\mathbf{p}_m = [p_m(1), \dots, p_m(n), \dots, p_m(N)]$ and $\mathbf{p}_k = [p_k(1), \dots, p_k(n), \dots, p_k(N)]$, respectively, where $p_m(n) \geq 0$ and $p_k(n) \geq 0$ are the transmit powers of MBS m and SBS k on subchannel n , respectively. For each MBS and SBS, the total transmit power is limited by

$$\sum_{n=1}^N p_m(n) \leq P_m^{\text{sum}}, \quad \sum_{n=1}^N p_k(n) \leq P_k^{\text{sum}}, \quad (2)$$

where P_m^{sum} and P_k^{sum} are the corresponding power budgets.

The MBSs and SBSs are considered to be of self-interest aiming to maximize their own achievable rate through the allocation of transmit power over the N subchannels subject to certain power and interference constraints. Given the power allocations of all MBSs and SBSs, the interference plus noise experienced by users of MBS m and SBS k on channel n can be expressed as $v_m(n) = \sigma_m^2(n) + \sum_{l \neq m} g_{lm}(n) p_l(n) + \sum_{k=1}^K h_{km}(n) p_k(n)$ and $v_k(n) = \sigma_k^2(n) + \sum_{m=1}^M h_{mk}(n) p_m(n) + \sum_{j \neq k} g_{jk}(n) p_j(n)$, respectively. Accordingly, the maximum downlink transmission rate for MBS m and SBS k can be obtained as follows:

$$\begin{aligned}
\mathcal{R}_m(\mathbf{p}_m, \mathbf{p}_{-m}, \mathbf{p}^{\text{low}}) \\
&= \sum_{n=1}^N \log(1 + p_m(n)/v_m(n)), \\
\mathcal{R}_k(\mathbf{p}_k, \mathbf{p}_{-k}, \mathbf{p}^{\text{up}}) \\
&= \sum_{n=1}^N \log(1 + p_k(n)/v_k(n)),
\end{aligned}$$

where $\mathbf{p}_{-m}$ and $\mathbf{p}_{-k}$ represent the power allocations of all MBSs except the m th MBS and power allocations of all SBSs except the k th SBS, respectively, $\mathbf{p}^{\text{low}}$ and $\mathbf{p}^{\text{up}}$ represent the vectors of power allocations of all SBSs and MBSs, respectively.

Robust Stackelberg Game Formulation

A robust Stackelberg game is formulated to capture the hierarchical competition among the MBSs and SBSs. Also, the competitive interactions exist within the multiple leaders and the multiple followers. In this case, a robust noncooperative leader sub-game for the leaders and a robust noncooperative follower sub-game for the followers are formulated. Both of them together constitute the robust Stackelberg game. Specifically, the structure of the robust Stackelberg game is described as follows:

- *Players:* The MBSs and SBSs are the players of the robust Stackelberg game. Also, the MBSs are the players (as the leaders) of the leader sub-game, and the SBSs are the players (as the followers) of the follower sub-game.
- *Strategy:* The strategy of each player (both the leaders and the followers) is the selection of power allocation over the N available sub-channels.
- *Strategy space:* Denote by $\mathcal{P}_m$ and $\mathcal{P}_k$ the sets of admissible power allocation of MBS m and SBS k , respectively. The strategy spaces of the leaders and the followers are then given by $\mathcal{P}^{\text{up}} = \prod_{m \in \mathcal{M}} \mathcal{P}_m$ and $\mathcal{P}^{\text{low}} = \prod_{k \in \mathcal{K}} \mathcal{P}_k$, respectively. The strategy space of the entire game is given by the Cartesian product $\mathcal{P}^{\text{up}} \times \mathcal{P}^{\text{low}}$. Note that $\mathcal{P}_m$ and $\mathcal{P}_k$ vary with different considerations of the constraints.

- *Uncertainty models:* Ellipsoidal uncertainty model is considered.
- *Robustness:* For robustness analysis, we consider the worst-case.
- *Payoff:* The payoffs of the MBSs and SBSs are defined as $\pi_m = \mathcal{R}_m(\mathbf{p}_m, \mathbf{p}_{-m}, \mathbf{p}^{\text{low}})$ and $\pi_k = \mathcal{R}_k(\mathbf{p}_k, \mathbf{p}_{-k}, \mathbf{p}^{\text{up}})$, respectively.

Robust Stackelberg equilibrium (RSE) is considered to be the solution of the game which is constituted by a robust Nash equilibrium (RNE) of the leader sub-game $\mathbf{p}^{\text{up}*}$ and a RNE of the follower sub-game $\mathbf{p}^{\text{low}*}(\mathbf{p}^{\text{up}*})$ and is represented by the tuple $\{\mathbf{p}^{\text{up}*}, \mathbf{p}^{\text{low}*}(\mathbf{p}^{\text{up}*})\}$.

Robust Follower Sub-game

Backward induction is commonly used to analyze a Stackelberg game. Therefore, we start analyzing the robust Stackelberg game by firstly investigating the robust follower sub-game given the strategies of the leaders. Firstly, the admissible strategy set of SBS k is

$$\begin{aligned}
\mathcal{P}_k &= \left\{ \mathbf{p}_k \in \mathbb{R}^N : \sum_{n=1}^N p_k(n) \leq P_k, p_k(n) \geq 0 \right\}, \\
&\forall k \in \mathcal{K}.
\end{aligned}$$

The nominal formulation of the follower sub-game is described as follows. Given the power allocations $\mathbf{p}^{\text{up}}$ of the leaders, each follower k aims to maximize its own achievable downlink transmission rate as

$$\begin{aligned}
&\max_{\mathbf{p}_k} \mathcal{R}_k(\mathbf{p}_k, \mathbf{p}_{-k}, \mathbf{p}^{\text{up}}) \\
&\text{s.t. } \mathbf{p}_k \in \mathcal{P}_k.
\end{aligned} \tag{3}$$

The robust counterpart of the nominal game can be formulated by considering uncertainties in the channel state information. Specifically, each follower k aims to robustly maximize its downlink rate subject to CSI uncertainty which is a max-min problem described as follows:

$$\max_{\mathbf{p}_k} \min_{\mathbf{g}_k, \mathbf{h}_k} \mathcal{R}_k(\mathbf{p}_k, \mathbf{p}_{-k}, \mathbf{p}^{\text{up}}) \quad (4)$$

$$\text{s.t. } \mathbf{p}_k \in \mathcal{P}_k, \mathbf{g}_k \in \mathcal{G}_k, \mathbf{h}_k \in \mathcal{H}_k, \quad (5)$$

where $\mathbf{g}_k = \{g_{jk}\}_{j \neq k, j \in \mathcal{K}}$ and $\mathbf{h}_k = \{h_{mk}\}_{m \in \mathcal{M}}$. $\mathcal{G}_k$ and $\mathcal{H}_k$ are the information uncertainty sets

$$\mathcal{G}_k = \left\{ \bar{g}_{jk}(n) + \Delta g_{jk}(n), \|\Delta g_{jk}(n)\|_{\mathbf{w}_{jk}(n)} \leq \epsilon_k^2(n) \right\}_{j \neq k, j \in \mathcal{K}},$$

$$\mathcal{H}_k = \left\{ \bar{h}_{mk}(n) + \Delta h_{mk}(n), \|\Delta h_{mk}(n)\|_{\mathbf{w}_{mk}(n)} \leq \epsilon_k^2(n) \right\}_{m \in \mathcal{M}}.$$

With the ellipsoidal uncertainty model, for worst-case analysis, the problem in (4) can be transformed as

$$\max_{\mathbf{p}_k \in \mathcal{P}_k} \hat{\mathcal{R}}_k(\mathbf{p}_k, \mathbf{p}_{-k}, \mathbf{p}^{\text{up}}) \quad (6)$$

of player k . Note that since there is only power constraint, the uncertainties appear only in the payoff function.

The ellipsoidal uncertainty sets for follower k are modeled as

$$\hat{\mathcal{R}}_k(\mathbf{p}_k, \mathbf{p}_{-k}, \mathbf{p}^{\text{up}}) = \sum_{n=1}^N \log \left(1 + \frac{p_k(n)}{\hat{v}_k(n)} \right), \quad (7)$$

and

$$\begin{aligned} \hat{v}_k(n) = & \sigma_k^2(n) + \sum_{m=1}^M \bar{h}_{mk}(n) p_m(n) + \sum_{j \neq k} \bar{g}_{jk}(n) p_j(n) \\ & + \epsilon_k(n) \sqrt{\sum_{j \neq k} \frac{|p_j(n)|^2}{w_{jk}(n)}} + \epsilon_k(n) \sqrt{\sum_{m=1}^M \frac{|p_m(n)|^2}{w_{mk}(n)}}. \end{aligned} \quad (8)$$

The derivation is omitted here for brevity. Given the strategies of the MBSs and all other SBSs, the optimization problem in (6) is still convex. Applying the KKT optimality conditions, a closed-form solution for the robust power control can be obtained, which is a water-filling-like solution, given as

$$\mathbf{p}_k^* = [\mu_k - \hat{v}_k(n)]^+. \quad (9)$$

Robust Leader Sub-game

In the formulated robust Stackelberg game, the leaders need to anticipate the best responses of the followers in terms of the RNE of the follower sub-game. In this case, the leader sub-game becomes a robust equilibrium problem with

equilibrium constraints (EPEC). And for each MBS m , the robust rate maximization problem becomes a mathematical program with equilibrium constraints (MPEC) which can be expressed as follows:

$$\max_{\mathbf{p}_m} \min_{\mathbf{g}_m, \mathbf{h}_m} \mathcal{R}_m(\mathbf{p}_m, \mathbf{p}_{-m}, \mathbf{p}^{\text{low}*}(\mathbf{p}^{\text{up}})) \quad (10)$$

$$\text{s.t. } \mathbf{p}_m \in \mathcal{P}_m, \mathbf{g}_m \in \mathcal{G}_m, \mathbf{h}_m \in \mathcal{H}_m,$$

$$\mathbf{p}_k^*(\mathbf{p}^{\text{up}}) = \arg \max_{\mathbf{p}_k \in \mathcal{P}_k} \min_{\mathbf{g}_k \in \mathcal{G}_k, \mathbf{h}_k \in \mathcal{H}_k}$$

$$\mathcal{R}_k(\mathbf{p}_k, \mathbf{p}_{-k}, \mathbf{p}^{\text{up}}), \forall k, \quad (11)$$

where $\mathcal{P}_m = \left\{ \sum_{n=1}^N p_m(n) \leq P_m, p_m(n) \geq 0 \right\}$ is the power constraint for MBS m and (11) is the equilibrium constraint.

Robust Games for Power Control in Multi-tier Cellular Networks, Fig. 1 The normalized average rate of leaders

Robust Games for Power Control in Multi-tier Cellular Networks, Fig. 2

The aggregate interference experienced by a user of an MBS under different solutions

R

The uncertainty sets for leader m are expressed as

$$\mathcal{G}_m = \left\{ \bar{g}_{lm}(n) + \Delta g_{lm}(n), \|\Delta g_{lm}(n)\|_{\mathbf{w}_{lm}} \leq \epsilon_m^2(n) \right\}_{l \neq m, l \in \mathcal{M}}.$$

The uncertainty sets for the followers are shown in Section III.

Denote by $\mathbf{p}^{\text{up}*}$ an RNE of the leader sub-game, and then the tuple $\{\mathbf{p}^{\text{up}*}, \mathbf{p}^{\text{low}*}(\mathbf{p}^{\text{up}*})\}$ constitutes a robust Stackelberg equilibrium (RSE) which is considered to be the solution of the robust Stackelberg game. We first show the existence of a RSE in the following theorem.

Theorem 1 *There exists at least one robust Stackelberg equilibrium for the formulated*

multiple-leader multiple-follower robust Stackelberg game with ellipsoidal uncertainty model.

Given the leaders' strategies $\mathbf{p}^{\text{up}}$, the followers respond with the unique optimal power allocation $\mathbf{p}^{\text{low}*}$ (assuming that the uniqueness condition of the follower game is satisfied), which can

be numerically obtained. Then each leader m updates its strategy according to the following equation:

$$p_m(n) = \mu_m - \hat{v}_m(n), \quad (12)$$

where

$$\hat{v}_m(n) = \sigma_m^2(n) + \sum_{l \neq m} \bar{g}_{lm} p_l(n) + \sum_{k=1}^K \bar{h}_{km} p_k^*(n) + \epsilon_m(n) \sqrt{\sum_{l \neq m} \frac{|p_l(n)|^2}{w_{lm}(n)}} + \varepsilon_m(n) \sqrt{\sum_{k=1}^K \frac{|p_k^*(n)|^2}{w_{km}(n)}}.$$

Accordingly, an algorithm for reaching the RSE of the game is proposed as shown in Algorithm 1.

Algorithm 1: Algorithm for reaching the RSE

1. Initialization: set $i = 0$, each MBS chooses an initial power allocation $\mathbf{p}_m^i$.
 2. Given the power allocation of all MBSs $\mathbf{p}^{\text{up}}(i)$, each SBS k responds with the unique power allocation $\mathbf{p}_k^*(i)$.
 3. With the best response power allocations of the followers, and given the power allocations of other MBSs, each MBS m updates its power as $p_m^{i+1}(n) = \mu_m - \hat{v}_m^i(n)$.
 4. Repeat steps 2 and 3 until termination condition is satisfied.
-

Numerical Analysis

The performances of robust solutions and nominal solutions are evaluated in a scenario where the CSI is imperfect. The average rates of the leaders are shown in Fig. 1. It can be observed that with uncertainty in channel information, the robust solutions offer better performances than the nominal solutions. The performance gap increases with an increase of the degree of uncertainty.

Figure 2 shows the interference experienced by the leaders in each subchannel. It can be observed that the interference constraint could be violated if nominal solutions are used in an imperfect CSI environment. With the robust

solutions, the interference constraints can be satisfied for each subchannel.

Synonyms

Vehicle-to-everything (V2X); Vehicular ad hoc networks

Definition

A self-organized network that uses wireless communication technology to connect mobile vehicles and traffic facilities.

Historical Background

Since early 1980s, wireless communications had been utilized to connect vehicles to support road safety applications. Since there was no wireless communication standard suitable for such scenario, in 1992, dedicated short-range communication (DSRC) was suggested by the American Society to support the wireless communications among vehicles. In 2001, Vehicular Ad Hoc Networks (VANET) was first introduced (Toh 2002) as an application of the mobile ad hoc networks (MANETs). From then on, VANETs had been an independent research field. Latter in 2004, the 802.11p task group in IETF (Internet Engineering Task Force) was formed to draft the 802.11p standard, which became the most significant DSRC technology. By July 2010, after 11 revisions, the IEEE 802.11p standard was published. Later in 2015, a summary of all Vehicle-to-Vehicle (V2V) and Vehicle-to-Infrastructure (V2I) standards in use was published, including the systems specified by ETSI (European Telecommunications

Standards Institute), IEEE (Institute of Electrical and Electronics Engineers), ARIB (Association of Radio Industries and Businesses), and TTA (Telecommunications Technology Association) (ITU 2015). In 2017, as a contender of 802.11p, LTE-V (Long-Term Evolution-Vehicle) physical layer standards for V2I and V2V communication, which use a radio technology different from IEEE 802.11 WLAN standards, was proposed by the 3GPP.

Foundations

Vehicular ad hoc network, also known as vehicular network utilizing vehicle-to-everything (V2X) communication technology, is a special type of MANET. In MANETs, wireless devices form self-organized wireless networks in movement and transfer data in a multihop manner. More specifically, each device in a MANET can function as packet source, destination, and also router to forward packets for neighboring devices in its communication range. In VANETs, vehicles traveling in cities or along highway act as mobile nodes and form self-organized wireless networks on the fly while moving.

In a VANET, traffic-related and driving safety information can be shared among vehicles in the vicinity directly or with the assistance of fixed road side units (RSUs) (see Fig. 1 for

Routing for Vehicular Ad Hoc Networks, Fig. 1 A typical VANET scenario

illustration purpose). Also, VANETs can work as an extension of the fixed infrastructure to assist vehicles to access the Internet or cellular networks. Massive applications have been deployed or assessed by research institutions and consortia. Typically, VANET applications can be categorized as safety, transport efficiency, and information/entertainment applications (Hartenstein and Laberteaux 2008).

Various wireless technologies can be used in VANETs to support the short-range communication among vehicles and RSUs, such as DSRC, LTE-V2X. Among these standards, DSRC based on IEEE 802.11p has been commercialized by many companies including Toyota, General Motors, and Volkswagen AG (http://www.greencarcongress.com/connected_vehicles/). The IEEE 802.11p standard is an extension of the IEEE 802.11a standard and it was originally designed to handle some special requirements in V2X communication, such as fast message spreading and quick connection establishment in local areas. The Federal Communications Commission (FCC) of USA has allocated 75 MHz bandwidth to V2X communications in the 5.9 GHz frequency band.

Like typical MANETs, in VANETs, data packets are forwarded in a hop-by-hop manner among moving vehicles. Since vehicles move fast and travel in long distance, data sources and destinations may be far away from each other. Since IEEE 802.11p link is range-limited, in most cases, there typically exists no connected routing path between data source and destination (Mohammad et al. 2011). To transfer data in such intermittent connected networks, VANET uses a “store-and-forward” data forwarding pattern which was first introduced in the Inter Planetary Internet (IPN) to transfer data on unreliable links (Fall and Farrell 2008). According to such “store-and-forward” pattern, when there is no available next-hop, current packet holder will temporarily store the packets locally and wait for a communication opportunity to encounter a good next hop. For VANETs, vehicles that act as relay nodes store data packets when moving, so the “store-and-forward” process is also referred to as “store-carry-forward.”

In some cases, the multihop data forwarding in a connected wireless ad hoc network, the forwarding process is also called synchronous routing. In contrast, the “storage-carry-forward” mode in intermittently connected VANET is called asynchronous routing.

For the “store-carry-forward” pattern, the key of routing process is to find next-hop vehicles that are suitable/efficient for delivering data than the vehicle carrying the data packets. For different application scenarios, routing metrics may vary. So it is critical to convert specific routing metrics to routing rules that can assess vehicles’ capabilities of delivering data packets. According to the knowledge required in this process, VANET routing mechanisms can be roughly divided into three categories, namely, replica diffusion based routing, geographical routing, and sociality based routing.

In replica diffusion based routing, vehicles forward data through spreading copies of original data packets in the network. Once a copy is received by the final destination, the message is said to be successfully delivered. In this case, producing more data copies in the network can lead to higher delivery ratio, but also incur excessive resource consumption. In geographical routing, packet holding vehicles always send data to encountered vehicles that are currently driving approaching target nodes’ locations in a hop by hop manner. This type of forwarding strategy requires target nodes to continuously disseminate their fresh position information for relaying vehicles to learn such information during the routing process. For sociality-based routing, since each vehicle’s movement is controlled by a driver, and hence affected by the driver’s social attributes, relaying vehicles are selected from a social view. For example, vehicles that meet each other frequently are also likely to meet each other in future. This is because their drivers are likely to share some common social attributes, such as personal interests, or living and working area. Compared with replica diffusion-based routing and geographical routing, sociality-based routing usually has fewer transmission hops and higher packet delivery rates, but usually experiences much longer delivery delays. For different appli-

cation scenarios, it is necessary to choose one or even combinations of several routing methods to meet actual application requirements.

In addition to general end-to-end data forwarding, there are also more routing demands in VANETs. For example, in a lot of research work, VANET is used as an extension to the fixe infrastructure network to distribute messages on roads, or used as large scale mobile sensing system to collect vehicle status as well as traffic-related information in the city through sensors mounted on vehicles. For data diffusion applications, pub-sub (i.e., publish-subscribe) messaging pattern can be adopted and content-based routing is often preferred in such cases. For large scale data collection applications, vehicles only need to upload their collected data through RSUs distributed in the city, and this type of message routing process is also known as anycast routing, which is different from point-to-point data forwarding, which occurs between specific source-destination pair.

Key Applications

Vehicular Ad Hoc routing technologies are used to support decentralized networking and communication between vehicles, especially for geographical long-distance data forwarding in urban environments.

MIMO satellite

Definitions

A promising satellite communication (satcom) technique based on the applications of traditional multiple-input multiple-output (MIMO), which generally includes single-satellite MIMO and multi-satellite MIMO.

Historical Background

During the past decades, the intensive researches in MIMO technology in terrestrial applications have spanned worldwide with abundant and

spectacular results. Besides time and frequency domain, MIMO-based systems explore and reveal more resources through spatial domain and are able to greatly enhance the system spectrum efficiency via large-scale antennas, without any extra transmission power. It is universally acknowledged that MIMO is one of the most substantial techniques incorporated in the fourth-generation (4G) communication networks to achieve higher throughput and spectrum efficiency, which have been widely standardized in terrestrial communication systems, such as IEEE 802.20, 802.22, 802.11n, 802.16e, 802.16m, etc.

In early studies of satellite architectures, only single antenna with one fixed broad beam is considered. With the increasing demands of communication throughput and services, the great progress in terrestrial MIMO techniques motivates engineers to graft the strengths of multi-antennas onto satcom, which thereby impels the dramatic utilization increase of multibeam satellites to support high-speed transmission with spectrum reuse nowadays (Arapoglou et al. 2010). Moreover, the applications of multi-satellite clustering, as an extension of single-satellite MIMO systems, attract substantial interests of researchers and engineers around the world. Besides the contributions of single-satellite MIMO systems, different satellites can work cooperatively to serve multiple users and form a virtual MIMO system. In this way, the system can benefit from MIMO transmission even with single antenna

Satellite MIMO, Fig. 1

The architecture of single-satellite terrestrial multibeam system

being equipped, which is of great significance for satellites and ground terminals that are not capable for multiple antennas due to hardware or environment restraints.

In future 5G, apart from higher data rate request, it is expected that MIMO performs as flexible support technologies for satellite networks to meet the demands of data distribution, which enable to off-load part of the traffic and optimize the infrastructure dimensioning. Besides, multi-polarization MIMO is suitable for satellite- and context-aware multiuser detection, and massive MIMO plays an important role in satellite multibeam techniques and interference cancelation between multiple adjacent spot beams.

Foundations

Considering the different orbits, number of satellites, or functions of satellite terminals, the MIMO infrastructure between satellites and terrestrial networks should be designed carefully based on service coverage, transmission delay, link geometry, channel impairments, special interference, etc. Besides, the distinct differences of the channel characteristics between satcom and terrestrial communication systems also play significant roles in satellite MIMO applications. For example, the signals in urban areas with rich scatters and obstructions are dominated by multipath components, while in satcom systems, channels are always considered to be the line of sight (LOS) with little scatter.

A typical single-satellite MIMO multibeam system is illustrated in Fig. 1. The satellite generates multiple beams with certain frequency reuse. The ground terminals, assumed to be equipped with only one antenna, are randomly distributed over the area covered by multibeam spots. Users of adjacent beams are allocated with different frequencies. However, thanks to the nature of multibeam, proper frequency reuse pattern can be determined for higher spectrum efficiency.

One of the motivations of multi-satellite transmission is the limited space and spectrum resources in satcom systems, especially in the geostationary orbit. Therefore, letting multiple satellites share the same orbit window greatly releases the burden of orbit and spectrum resources. There are already a lot of studies concentrating on this aspects, such as the works of Robert T. Schwarz since 2008 (Schwarz et al. 2008, 2011). A typical 2×2 multi-satellite MIMO cooperative transmission system where the satellites share the same orbit window is given by Fig. 2. In the system, the selected users transmit signals simultaneously to collocated satellites in the same frequency allocated by the ground control center. Then the satellites forward the received signals to the ground control center through another wide-bandwidth link for signal processing. It is shown that the capacity of satellite MIMO transmission can be further enhanced by using multiple satellites for cooperative transmission.

Another aspect of multi-satellite MIMO transmission is the distributed satellite clusters. This architecture is becoming increasingly attractive in

Satellite MIMO, Fig. 2 The architecture of multi-satellite MIMO cooperative transmission system

the researches of space information networking (Yu et al. 2016), as shown in Fig. 3. The system aims at overcoming communication network heterogeneity and realizing information interaction between different systems in the future. Rather than sharing the same orbit in space, distributed satellite cluster architecture contains a larger map where satellite clusters are separately distributed in different orbits. Satellite clusters can exchange information between each other and work cooperatively to accomplish complex tasks.

Key Techniques

From the architecture of satellite MIMO systems, communication technologies in common terrestrial MIMO systems, such as power allocation strategies, precoding/decoding procedure, user scheduling, etc., are supposed to jointly design to achieve a good balance between resource constraints and the quality of service (QoS) of scheduled user terminals.

As illustrated in Fig. 4, resource allocation and channel estimation are major concerns in single-satellite MIMO transmission. Further, for multi-satellite systems, more advanced schemes such as virtual MIMO and distributed satellite cluster also attract much attention around the world.

Resource Allocation

Reasonable resource allocation among multiple users with required QoS is crucial to meet the demand of larger throughput and increasing number of accessing users in future communications. The resource allocation in satcom systems includes power/bandwidth/time-slot allocation, beamforming/precoding schemes, and user clustering/subgrouping.

- Power allocation
 - The evaluating indicators of various power allocation strategies contain the total system throughput, the SINR balancing between different users, and energy efficiency. There have been abundant studies on power allocation in satcom systems, most of which concentrate on one of the indicators, such as sum-rate maximization in certain QoS of users, power minimization, or max-min SINR request. However, the fast evolution of communication markets and the demands of the next-generation targets urge satellite systems to be competitive in the advent of multimedia interactive services. Therefore, the power allocation should be more adaptive and flexible for future satcom systems.

Satellite MIMO, Fig. 3 The architecture of space information networking

- Beamforming/precoding
 - There are two concerns in satellite MIMO beamforming: achieving better capacity performance and mitigating interference (including inter-beam and inter-beam interference), which are usually considered jointly to derive well-designed beamforming/precoding matrixes (Arti and Bhatnagar 2014). For early multibeam satellite systems, beamforming techniques are the extension of well-known terrestrial MIMO beamforming techniques such as linear precoding. With the increasing user scales, subgrouping schemes are used to spatially separate highly correlated users and guarantee orthogonality between different user groups. Afterward, digital beamforming is applied to generate multibeam for different user groups, and other multiple access techniques are used to mitigate intragroup interference.
 - User scheduling
 - A reliable user scheduling strategy should achieve higher transmission quality for each scheduled users, take a good balance between the spectrum efficiency and fairness, and mitigate the inter-beam/inter-cluster interference. In recent researches, more sophisticated scheduling schemes are proposed in satellite multicast systems to realize good balance between performance and complexity, such as the max-min heuristic principle considered in Boussemart et al. (2011).
- Multicast multigroup beamforming is another widely studied field in satcom

Satellite MIMO, Fig. 4 Key techniques in satellite MIMO systems

systems to further reduce interference and improve system performance. Early multicast multigroup beamforming is based on a simple strategy that serves all the users in one spot beam as a single user, and thus the same symbol is broadcasted with multiple users. Afterward, more sophisticated multicast multigroup beamforming schemes based on block singular value decomposition (SVD) (Orsino et al. 2017) or joint optimization, such as frame-based (Christopoulos et al. 2015), are considered to provide better performance.

Channel Estimation

Large amounts of studies demonstrate that the impact of imperfect channel state information (CSI) in satcom systems is the interaction between a series of factors, such as system modeling, channel states (including weather, scattering, etc.), modulation mode, the applied channel estimation strategies, beamforming/decoding schemes, and so on. That results in

degradations of performance such as SER, BER, capacity or effective capacity, etc. (Arti 2016). Meanwhile, multi-antenna structures play a non-negligible role in combat with imperfect CSI. A larger number of antennas can improve the system performance significantly. For satellite MIMO systems, training data-based channel estimation strategies for terrestrial MIMO are still capable, such as symbol-aided (SA) algorithm, symbol-aided plus decision-directed (SADD) algorithm, and decision feedback and adaptive linear prediction (DFALP).

Virtual MIMO and Distributed Satellite Clustering

It has already been demonstrated that orthogonal MIMO channel formulation via the explicit positioning of satellite and user antennas can dramatically improve the capacity of satcom systems, as extra spatial multiplexing gain is obtained by forming virtual MIMO systems between satellites and terminal users. For distributed satellite cluster networks, the resource management between different clusters is a

crucial concern. In comparison with single-satellite systems, the distributed satellite cluster networks can be a dynamic, diverse, and complicated network. Therefore, higher dynamic multi-objective joint allocations of network resource are demanded to satisfy different requirements.

[Scalable streaming media](#); [Scalable video coding](#)

Definition

Scalable video streaming is a new type of adaptive video communication technology based on the scalable video coding and transmission rate control, which make the video communication adaptive to complex multimedia application environments, heterogeneous networks, and different user requirements. The scalable video coding technique is employed to generate the multi-rate streaming videos from the original video files. The transmission rate control technology is employed to dynamically adjust the transmission rate of the streaming videos. Therefore, the

smooth playback can be ensured, while improving the video quality and the user experience.

Historical Background

According to the forecast of American Information Company (Cisco 2014), the video business will account for 80% of the entire Internet data traffic until 2019. From the statistical data, there is an increasing demand for the network multimedia services. Due to the existing problems of the IP-based network architecture, such as the constrained bandwidth and unstable connection, adaptive network management and scheduling strategy is an effective way to design the reliable media service system. The scholars have made many studies, including the adaptive transmission control technology, the adaptive video transcoding, and the media processing technology, such as the scalable video coding (SVC).

The adaptive transmission control and video transcoding allows users to dynamically adjust video frame rates within a certain range. This mechanism can effectively compensate the influence of the network jitter on the video playback, so as to reduce the playback delay, interruption, and improve the user experience. Kalman et al. (2004) and Chuang et al. (2007) used a strategy based on the fixed buffer threshold to trigger the adjustment of the playback rate. Liu et al. (2008) has proposed a H.264 bit allocation strategy based on the rate-distortion (R-D) model. The scalable coding technology encodes videos in the time, space, and quality dimensions as a base layer and multiple enhancement layers. The more video layers the user receives, the higher the corresponding video code rate is, and the better the video quality is. Nejati et al. (2010) established a scalable expected video transmission distortion model in wireless channels and solved the video transmission optimization problem to minimize the distortion.

In recent years, the researches that combine the future network and video streaming has received extensive attentions, which focus on the separation of control and data forwarding, the content centric network, and the in-network

cache. Egilmez et al. (2013) designed a quality of service-enabled (QoS-enabled) scalable video transmission framework for the openflow network. Yang et al. (2018) implemented the adaptive multicast scheme in the software defined network (SDN), where the combination of the media streaming and programmable network can provide better multimedia services. Li and Simon (2011) proposed a collaborative cache strategy for the content centric network (CCN) to alleviate the bandwidth pressure caused by the centralization of a large number of user requests. Rao et al. (2013) considered the active and proactive caching of part data in the named data network (NDN), which was able to better support the user mobility.

Foundations

Architecture of the Network Multimedia Service System

The architecture of the traditional network multimedia service system can be divided into two types, which are the connection-oriented streaming media based on the real time streaming protocol (RTSP) and the connectionless progressive downloading based on the hypertext transfer protocol (HTTP).

In the connection-oriented streaming media system, the server always monitors the client state while sending the media data packet and responds to the client feedback in real time. During the streaming media transmission, the client uses the RTSP protocol to transmit the control commands to the server, such as play, pause, setup, and teardown. The media data packets are carried by the real-time transport protocol (RTP), while the RTP connections are controlled by the real-time transport control protocol (RTCP), and the required network resources are provided by the resource reservation protocol (RSVP). By this way, the online real-time video playback can be guaranteed, and the server can adaptively adjust the media bit rate according to the client feedback. However, the installation, configuration, and maintenance of the streaming media servers are complicated and expensive. HTTP is

a stateless protocol that does not maintain the connection state between the client and the server, and the client can choose to play from any time in the undownloaded video file. The connection-less progressive downloading system is generally applicable to the video on demand services, and is supported by the mainstream terminal players. This framework is scalable, compatible, and flexible to deploy but does not support the live video broadcast services. Due to the lack of media adaptivity, the quality of experience in a wireless network environment is poor.

To solve above problems, the HTTP adaptive streaming (HAS) technology has emerged. Since the media data is transmitted by the HTTP, it has the good compatibility, strong scalability, and flexible deployment. Meanwhile, the same media content is encoded into multiple code rate counterparts, the client can select the appropriate version based on its own network conditions and improve the media adaptivity.

Media Adaptive Technology

Recently, the high-definition multimedia services are required to provide the higher quality of service (QoS) and the better quality of experience (QoE). However, different terminals have different resolution and decoding capabilities, and different access networks have different bandwidths, delays, and packet loss rates, which pose a huge challenge to the development of network multimedia services. To overcome this challenge, the adaptivity of the media content is becoming more and more important. The following three methods can be used to improve the adaptivity.

The online adaptive transcoding method is a technology that dynamically changes the encoding parameters, such as the frame rate, spatial resolution, and the like, before transmitting the

compressed video stream to the client. The original stream is thus converted into a different video stream with different frame rates and resolutions. The schematic diagram is shown in Fig. 1. By adjusting the frame rate, spatial resolution, and image quality, the method can convert the high quality video stream into a low-quality version, or convert the low-quality video stream into a high-quality version. Therefore, the online transcoding can enhance the media adaptivity, support heterogeneous networks and terminals, different systems and formats.

The SVC is a method that can layer code the video stream in space, time, and quality, which has been included in the extended version of the H.264/AVC video codec standard and is known as the H.264-AVC standard. With the SVC, the original video is encoded into a multi-layer video stream with one base layer and multiple enhancement layers. The base layer has a small amount of data, low bandwidth requirements, and can be independently decoded to provide a barely acceptable viewing quality. As the number of enhancement layers increases, the bandwidth requirements increase gradually. Meanwhile, depending on the layering method, the video quality can be improved from the resolution, frame rate, and image quality. This layered approach greatly enhances the media adaptivity. The SVC video stream can support multiple heterogeneous networks and terminals, and can dynamically adjust the video stream as the network bandwidth changes.

The HAS system uses a multi-rate block coding method to enable media adaptation. In Fig. 2, a dynamic adaptive streaming over HTTP (MPEG-DASH) architecture is used to show the method. After the original video is encoded by the DASH encoder, it is compressed into a plurality of counterparts, which have the same

Scalable Video Streaming, Fig. 1 Online transcoding process

Scalable Video Streaming, Fig. 2 General structure of MPEG-DASH

video content but different code rates and quality. Each version of the video stream is sliced into a number of small video blocks in the time domain, and each video block is a file that can be decoded independently. The original video generates the corresponding media presentation description (MPD) file after encoding. Each video block corresponds to a uniform resource locator (URL) and is recorded in the MPD. When starting to transmit the video content, the client senses the network bandwidth to dynamically select an acceptable video bit rate, which is determined by comparing the bandwidth requirements of the different video versions in the MPD file. Then the serial number of the next video block after the current playing time is determined, and the URL of the corresponding video block can be found in the MPD file. Finally, the client can use the URL to initiate a video request. Since the video blocks are sequentially requested by the client in the time domain, the content between the video blocks is continuous and does not overlap, the video is seamless and smooth for the user to play.

QoS Evaluation of Adaptive Media

Traditional QoS metrics include the network latency, throughput, packet loss rate, bit error rate, jitter, and etc. These indicators reflect the performance of the network transmission layer but ignore the video characteristics and the subjective feelings of the users. Some QoS indicators from the user's perspective should be

defined to fully describe the adaptive multimedia services.

Ignoring the impact of users and the environment, when the video sources used are the same, the QoS mainly depends on factors, such as the video quality, smoothness of playback, and video. The video quality can be calculated by comparing each pixel of the original video frame with the distorted video frame to get the similarity or fidelity, which is represented by the average mean square error (MSE) and peak signal to noise ratio (PSNR),

$$MSE = \frac{\sum_{0 \leq i \leq M} \sum_{0 \leq j \leq N} (f_{ij} - f'_{ij})^2}{M \times N}, \quad (1)$$

$$PSNR = 10 \lg \frac{(2^n - 1)^2}{MSE}, \quad (2)$$

where M , N represent the height and width of the video frame, f_{ij} and f'_{ij} represent the original video frame and the distorted video frame, and n is the number of bits per sample. The video fluency also seriously affects the user's willingness to watch. The video fluency is mainly reflected by the interruption and the stuck in the playback process. Therefore, the average frame rate f_T and the interruption frequency f_C can be used to characterize the fluency in the practical applications,

$$f_{T'} = \frac{S(T)}{T'}, f_C = \frac{C(T)}{T}, \quad (3)$$

where $S(T)$ indicates the total number of frames when playing a video of length T , T' is the actual playback time, and $C(T)$ denotes the total number of interruptions during the playback process. The video viewing experience of the user depends not only on the image quality per frame but also on the quality fluctuation. Rapid image quality fluctuations will lead to the video flicker and reduce the QoE. For the smoothness of the video, the variance of the quality or code rate can be used to characterize,

$$\sigma^2 = \frac{\sum_{t=1}^T (r_t - \bar{r})^2}{T} \quad (4)$$

where T is the video duration, r_t is the code rate at time t , and $\bar{r}$ is the average code rate.

In addition to the QoS evaluation methods listed above, evaluating QoE from a user perspective is also an effective approach. Recently, the structural similarity (SSIM) based on a single image can quantize the video QoE, that is, by mapping the time-averaged SSIM onto the mean opinion score (MOS), the QoE can be obtained.

Key Applications

The scalable video streaming can be applied in the following two aspects:

- *Adaptive transmission of scalable video in wireless networks*

In a wireless network environment, the user mobility, channel interference, and time-varying background traffic will cause the random bandwidth changes. Therefore, the media rate adaptive algorithm based on the underflow probability is necessary for video transmission in a wireless network. The algorithm takes into account the bandwidth changes, the buffer state, the flicker effect on the QoE, and does not rely on the prior knowledge of any wireless channel and video information. Due to the discrete nature of

the scalable video bit rate, blindly increasing the number of layers is easy to cause the oscillation of the video quality. In order to overcome the oscillation, the variation of the code rate is defined as the perturbation factor, and the perturbation analysis model is introduced to evaluate whether the change of the code rate causes the oscillation of the quality. Thereby the blind switching of the video can be avoided and the switching rate can be effectively reduced. The adaptive algorithm based on the underflow probability can significantly improve the smoothness of the video playback while ensuring the video quality.

- *Joint optimization of routing and rate control under SDN architecture*

The SDN architecture has the characteristics that the network state is observable and the route can be dynamically configured. The joint video rate control and dynamic routing optimization algorithm provides self-aware, self-configuring, and self-optimizing multimedia services under the SDN architecture. The algorithm makes decisions based on the currently observed network state, such as the topology, throughput, and packet loss rate, without any prior information. In the video transmission process, the algorithm can adaptively adjust the bit rate and routing path based on the network conditions, which significantly enhances the QoS. Meanwhile, with the multipath transmission mode, the idle bandwidth resources in different paths can be effectively utilized to improve the video quality. Comparing with the fixed rate and routing algorithms, the joint optimization algorithm can effectively improve the video quality, reduce the packet loss rate, and increase the utilization of the bandwidth resources.

Future Directions

The emergence of various new technologies makes the network management and configuration more flexible and also provides a new opportunity for the development of network multimedia technology. Combining traditional

streaming technology with new network technology can optimize the transmission quality of multimedia services and improve the utilization efficiency of network resources, so as to establish self-aware, self-configuring, and self-optimizing network multimedia service system. The future work mainly focus on the following aspects:

- Multimedia service based on intra-network caching

With new network technologies, the routers have the computing and storage capabilities to process and cache all or part of the passing data. During the routing process, the cache on the router can be directly used as a data source to respond to the service requests, thereby avoiding the network congestion from the original data source, shortening the acquisition delay of the media content, and reducing the repeated transmission of data packets. Therefore, an appropriate caching strategy can enhance the resource sharing, improve the network utilization, and speed up the distribution of multimedia content. The core problem is to study the selection strategy of the caching nodes, the size of the allocated cache, and the media content to cache on the basis of the requests from the massive users. In addition, considering the mobility of users, proactively push the media content to the user's neighboring access nodes to solve the problem of seamless switching is also need to be concerned.

- Content-aware adaptive multimedia service

By naming the media content and separating the content identifier from the network address, the content attributes can be recognized, such as the real-time requirements, popularity, preset priorities, and etc. By introducing the measurement, feedback, prediction techniques, and stochastic optimization methods in modern control theory, the dynamic perception and prediction of the network resources and traffic load can be performed. Combining the network and media content attributes, the appropriate caching and routing strategy can be developed

to allocate the network resources, adjust the video bit rate, and optimize the transmission path.

Definitions

Software-defined network (SDN) is an emerging networking paradigm which separates the network's control logic (the control plane) from the underlying routers and switches (the data plane) and enables the network to be programmable, adjustable, and centralized controlled.

Historical Background

The history of SDN can be traced back to the active networks, which were widely studied

from the mid-1990s to the early 2000s. These techniques introduced programmable functions to dynamically adjust network configurations (Feamster et al. 2013). From around 2001 to 2007, the concept of control and data plane separation was proposed. In 2008, McKeown developed a standard application programming interface (API) between the control and data planes, i.e., the OpenFlow, which was regarded as the first practical and scalable instance of widespread SDN open interface (McKeown et al. 2008). Additionally, the Open Networking Foundation was founded in 2011 to further promote the development of OpenFlow and SDN. Recently, due to the high scalability and adjustability, SDN is adopted to data center networks (DCNs) to promote traffic transfer and management among servers (Son et al. 2018; Hafeez et al. 2017).

Foundation

A typical SDN consists of three main components: the centralized SDN controller, SDN-enabled switches, and hosts (Cui et al. 2016). The controller manages the control plane and is responsible for installing flow rules in the data planes of the network devices. It can also obtain the real-time states of the network using probes for specific network statistics. Generally, SDN architecture includes two main APIs, i.e., the southbound API and the northbound API. The former defines the interface between a controller and switches, while the latter defines the interface exposed by the controller to the network applications. DCN usually includes many switches and servers, which may generate large numbers of data flows. Therefore, some challenges may restrict the performance of DCN, e.g., the traffic congestion, energy consumption, and malicious attacks. SDN technology has been regarded an effective method to deal with the above challenges. Existing studies of SDN-enabled DCNs mainly consider three objectives, i.e., congestion control, energy efficiency, and security.

Congestion Control

Based on the state of the entire network, the centralized controller of SDN is able to provide fine-grained control in order to mitigate the traffic congestions in DCN. For example, the controller can detect the occurrence of traffic congestion and direct the traffic flows to a vacant path.

In Gholamiand et al. (2015), the SDN controller firstly gets statistics of ports and queues regularly. Once the buffer occupancy of a certain switch exceeds a preset threshold, the rerouting is conducted. The authors utilized OpenFlow platform to validate the proposed scheme. Moreover, as flows can be categorized into elephant flows (large size) and mice flows (small size), congestions control schemes on them are also different (Hafeez et al. 2017). For instance, Kanagevlu proposed a rerouting approach which identifies and labels flows larger than 100 KB (Kanagevlu et al. 2015). If the load of a certain link exceeds a preset threshold, the controller could install new flow rules to reroute several elephant flows to an alternate path.

Energy Efficiency

As DCN consumes enormous amounts of electricity, methods to improve energy efficiency have received much attention recently. Thanks to the SDN, the network elasticity is easy to be achieved.

In Heller et al. (2010), the authors proposed a power-saving scheme for the fat-tree network topology. Using this scheme, data flows can be consolidated into a smaller number of links, which provides possibilities to turn off unused switches and thus save considerable amount of energy. Moreover, the authors also evaluated the relationship among energy efficiency, transmission efficiency, and network robustness, under various traffic patterns extracted from real-world data traces. X. Wang et al. also studied the traffic consolidation-based energy-saving scheme for DCN (Wang et al. 2016). In this scheme, the correlation analysis is conducted based on the variation trends of traffic flows. Using the analysis results, the controller is able to place the flows with similar trends (i.e., hit the peak or trough at the same time) on the same

part of the network and dynamically turn off unused switches. Aujla et al. presented an SDN-based energy-aware flow scheduling algorithm, which considered the energy efficiency as one of the optimization objectives (Aujla et al. 2018). The multi-leader and multi-follower Stackelberg game theory was used to model and solve the problem. Evaluations were conducted on the Google workload traces to show the effectiveness of the proposed algorithm.

Security

DCN is also vulnerable for some malicious attacks, e.g., the distributed denial of service (DDoS) attack. By utilizing specific SDN functions, e.g., traffic analysis, centralized control, and dynamic update of network rules, the DCN can provide fast detection and reaction to malicious attacks.

In Xu et al. (2016), the authors designed an SDN-based DDoS detection system for data centers. The system consists of two parts: victim detection and post-detection. Firstly, the IP addresses of both victims and attackers are detected based on two flow features, i.e., flow volume and flow rate asymmetry. Then, rules can be installed in the SDN-enabled switches in order to drop packets from attackers to victims. In this way, the effects of DDoS attacks are significantly mitigated. Moreover, Chowdhary et al. proposed a security framework to prevent DDoS attacks for SDN-enabled DCN (Chowdhary et al. 2017). Due to the programmability of SDN, the authors designed a reward and punishment scheme using game theory. This scheme made the bandwidths of potential attackers to be downgraded for a certain period of time and restored back to normal if they resumed cooperation. Evaluations were conducted on various network topologies, e.g., linear topology and fat-tree topology.

Key Applications

SDN-enabled data center networks can provide high-performance, energy-efficient, and security solutions for cloud computing and big data applications.

[Secure association](#)

Definition

Device pairing (*pairing* for short) is the process of establishing a security association between two devices that share no prior knowledge. The security association, such as a shared secret key, is known only to the two devices and thus can

be used to protect subsequent communication between them.

Secure device pairing requires the pairing process to be resilient against a *man-in-the-middle* (MitM) attack, where an adversary attempts to impersonate at least one of the devices by eavesdropping on, intercepting, manipulating, or relaying messages between them.

Secure device pairing and *secure association* are frequently used interchangeably. Since pairing typically involves only two devices, *group device pairing* or *group association* has been used to indicate establishing a group key among three or more devices.

Background

Secure device pairing is crucial for initiating secure communication between previously unassociated devices. After performing secure device pairing, both devices can be assured of an established shared secret with the intended party, even in the presence of *man-in-the-middle* (MitM) attacks. Such an MitM adversary can overhear, intercept, manipulate, or relay messages sent between the devices.

Secure device pairing over a wireless channel with no infrastructure support is more challenging than over a wired one. This is due to the broadcast nature of wireless mediums, which makes the wireless channel highly susceptible to eavesdropping and manipulation. Furthermore, when applied to resource-constrained devices (e.g., a device with no output display), or devices operated by ordinary users without technical expertise, the pairing method must minimize additional input/output hardware and avoid complex user interaction. Hence, a long-standing challenge for secure pairing methods in wireless ad hoc settings is to achieve security, usability, and deployability simultaneously. For comparative surveys of secure device pairing methods, see Kainda et al. (2009), Kobsa et al. (2009), Kumar et al. (2009), Mirzadeh et al. (2014), Chong et al. (2014), and Fomichev et al. (2018).

Foundations

Secure device pairing methods can be broadly divided into two types, by whether a secondary channel is present or not. The secondary channel is typically referred to as an *out-of-band* (OOB) channel, opposite to the primary *in-band* channel. While the in-band channel is vulnerable to *man-in-the-middle* (MitM) attacks, the OOB channel is *assumed* to guarantee authenticity despite MitM threats. For example, the historically important secure device pairing protocols that were proposed in the 1990s and 2000s, including Resurrecting Duckling (Stajano and Anderson 1999), Talking to Strangers (Balfanz et al. 2002), Seeing-is-Believing (McCune et al. 2005), and Loud-and-Clear (Goodrich et al. 2006), use physical contact, infrared, visual, and audio channels as the OOB, respectively. Because the OOB channel usually has limited bandwidth capacity, it is mainly used for authenticating a small amount of data, such as the cryptographic hash of a public key, but is not meant to replace the high-capacity in-band channel.

Secure device pairing with OOB. After obtaining authentic information via OOB, the devices can then perform *authenticated key exchange* via the in-band channel to establish a shared secret. To understand how OOB facilitates secure device pairing in general, let us consider a common scenario in which the devices would like to establish a shared secret by performing the *Diffie-Hellman* (DH) key exchange over an in-band channel. The DH protocol is widely adopted and is resilient against passive eavesdroppers overhearing exchanged messages. However, the DH protocol is known to be vulnerable to MitM attacks, in which the attacker actively interacts with both devices and can intercept, manipulate, or relay messages in addition to eavesdropping. More specifically, without using an OOB channel to obtain authentic DH public keys, a MitM attacker can easily impersonate both devices without being detected, and the attacker establishes shared keys with each device separately by relaying messages between them both. On the other hand, by exchanging the DH public keys via an OOB channel, both devices can verify

whether they obtain the correct DH public key of the intended party. If the OOB channel not only guarantees authenticity but also secrecy, the devices may also derive a shared secret directly from OOB.

A wide spectrum of OOB channels have been explored, including Wi-Fi, Bluetooth, mm-waves, radio-frequency identification (RFID), near-field communication (NFC), visible light communication (VLC), visual, Infrared Data Association (IrDA), audio, ultrasound, haptic, and sensing (Fomichev et al. 2018). As explained above, OOB channels are *assumed* to guarantee authenticity despite MitM threats. When utilizing an OOB channel, a secure device pairing method must justify this assumption under reasonable application scenarios and adversary models. For example, NFC might be applicable as an OOB channel if the attacker is outside NFC's communication range and the devices are equipped with corresponding transceiver modules. As another example, the Line-of-Sight property provided by VLC and infrared makes it easy to detect MitM attacks, assuming that a user is present and vigilant enough to spot potential MitM attackers physically standing between the two devices.

Many secure pairing methods rely on human-perceivable OOB, including visual, audio, or haptic channels. The user must actively verify whether both devices agree on the exchanged information by comparing the displayed codes or lighting patterns on both devices, typing the displayed PIN on one device into the other, etc. For example, the pairing protocol in the Bluetooth Low Energy (BLE) standard supports two options that require active user involvement. In the *Passkey Entry* option, a 6-digit PIN code is displayed on one device, and the user inputs the PIN to the other. In the *Numeric Comparison* option supported by BLE4.2+, both devices display a 6-digit PIN code, and the user checks if the PIN codes match.

Because these pairing methods must interact with the user, they may be inapplicable for devices with limited input/output capabilities (e.g., ones without screens to display codes). In addition, the security of these pairing methods depends on the assumption that the user can

correctly follow the instructions, but in reality procedures involving users are often error-prone. As a result, when utilizing human-perceivable OOB, security is sometimes sacrificed in exchange for better user experience, such as a shorter pairing delay.

To reduce or even avoid user involvement, researchers have proposed secure pairing methods that rely on physically constrained OOB channels, which are assumed to be resilient against MitM attacks because of inherent physical constraints. For example, near-field communication (NFC) is a short-range radio-frequency channel typically operating in centimeter-level distance and thus can act as a location-limited OOB resilient against a remote MitM attacker.

Some physically constrained OOB channels leverage the similar contexts of co-present devices for authentication and even key establishment. The similarity in contexts can be seen as proof of physical proximity and can be used for deriving a shared secret key. For example, the user may be asked to shake both devices together, such that their accelerometer readings can be used to authenticate the devices and create a shared secret. As another example, the user can physically hold both devices at the same time, and a secret can be established via intra-body communication. Some context-based pairing methods require no user interaction by harvesting ambient contexts (Miettinen et al. 2014), such as acoustic, electromagnetic, luminosity, or channel state information (CSI), to name a few. As ambient sensing may take a long time to achieve a sufficient level of robustness and security, pairing methods often combine multiple sensing channels.

In-band only (secure device pairing without OOB). Because requiring a secondary channel might be impractical in some application scenarios, researchers have also considered in-band-only solutions to secure pairing (Gollakota et al. 2011). To mitigate MitM adversaries, in-band-only approaches often rely on the channel's physical properties and propose specific encoding or modulation schemes such that any alteration can be easily detected.

Secure pairing in a group. Several proposals extend the secure pairing problem to group settings (Lin et al. 2009). One variant considers secure pairing in a group, where devices want to obtain each other's authentic information, such as public keys. Another variant considers establishing one shared secret among all devices belonging to the same group. Although secure pairing in a group of n devices can be straightforwardly reduced to performing n^2 pairwise pairing, or n pairwise pairing with a trusted leader, they suffer from high latency and user burden. In addition, advanced attacks, such as group partition, need to be taken into consideration.

Device pairing in standardized wireless protocols. Bluetooth Low Energy (BLE) supports four authentication methods to secure key exchange during device pairing. Devices can negotiate and select one to use based on their I/O capabilities.

- *Just Works* provides no authentication.
- *Passkey Entry* displays a 6-digit PIN code on one device, and the user needs to type the PIN on the other.
- *Numeric Comparison*, introduced in BLE version 4.2, displays 6-digit PIN codes on both devices, and the user needs to confirm that they are identical.
- *Out-of-band (OOB)* is directly provided with a shared key and assumes the key has been securely established via an alternative OOB channel.

Wi-Fi Protected Setup supports four modes for pairing a new wireless device and access point: *PIN*, *Push Button*, *NFC*, and *USB*. While supporting the PIN mode is mandatory, it has been shown that PIN-based WPS is vulnerable to simple brute force attacks due to flawed protocol design and should be disabled for security.

Key Applications

Secure device pairing is mainly used for bootstrapping secure communication between previ-

ously unassociated devices in an ad hoc manner.

Secure Routing in Cognitive Radio Vehicular Ad Hoc Networks

Ying He

Department of Systems and Computer Engineering, Carleton University, Ottawa, ON, Canada

Synonyms

[A securing routing scheme for vehicular networks with cognitive radios](#); [Security in vehicular networks with cognitive radios](#)

Definitions

This topic mainly talks about a trust-based routing scheme for ad hoc vehicular networks with cognitive radios to effectively improve security for both spectrum sensing and data transmission processes.

Historical Background

In previous works, it is generally assumed that a spectrum-sensing attacker will only attack the spectrum sensing process in CR networks, and a data transmission attacker will only attack the data transmission process (Yu et al. 2009). However, it is highly possible for an intelligent attacker to attack both processes in CR-VANETs.

Vehicle Ad Hoc Networks

Recently, there is a phenomenal burst of interest in connected vehicles (CVs). CV systems use

connectivity (via advanced wireless communications) to enable vehicles, smart roadway infrastructure (SRI), and personal mobile devices to exchange information with each other and to provide road users with both safety and mobility advisories, warnings, and alerts (Yu 2016; He et al. 2018b). Vehicular ad hoc networks (VANETs) as the basic infrastructure can facilitate applications and services of CVs and intelligent transportation systems (Bravo-Torres et al. 2016; He et al. 2017). One of the main challenges in VANETs is the issue of limited resources, including radio spectrum resources, computation and storage resources, etc.

Cognitive Radio VANETs

For the limited radio spectrum issue, a promising solution is cognitive radio (CR) (Haykin 2005; Yu 2011), which has already extended to vehicular network environments (Haykin 2005). Generally, CR technology can help secondary users (SUs) that have no predefined spectrum for wireless communications to utilize the primary users (PUs) licensed spectrum. The condition is that the SUs should not interrupt the PUs normal communications. In other words, the interferences from the SUs are not allowed to produce a negative effect on PUs performance. In vehicular networks, CR technology can be used to mitigate the spectrum limitation issue, and when CR technology is introduced into VANETs, it is called CR-VANETs. In CR networks, there are two main processes: spectrum sensing and data transmission (Zhang et al. 2017). In the spectrum sensing process, mobile nodes detect the radio bands that are not utilized by PUs. In the data transmission process, data packets are transmitted using the detected idle radio bands.

Securing Routing in CR-VANETs

Both spectrum sensing and data transmission suffer many potential malicious attacks in CR-VANETs, such as incumbent emulation (IE) attack and spectrum sensing data falsification

(SSDF) attack (Sharifi and Niya 2016) in spectrum sensing, and packet dropping/modification attacks in data transmission. In an IE attack, an attacker can mimic a false signal of the PU in order to disturb the spectrum sensing process. In an SSDF attack, an attacker can disturb the SUs spectrum sensing results by disseminating fault spectrum sensing results deliberately in order to result in a wrong decision of the presence/absence of PUs. A packet dropping attack is also called as a black hole attack, which is a type of denial-of-service attacks (Djahel et al. 2011). In addition, packet modification of packets may have a significant impact on the performance of a network (Li and Trappe 2006).

Although some excellent works have been done to address spectrum sensing security and data transmission security in CR-VANETs, these two important areas have mostly been addressed separately in the existing works. In He et al. (2018a), an integrated framework is proposed to study trust management so as to enhance security for both spectrum sensing and data transmission processes in CR-VANETs. Additionally, a trust-based routing scheme for securing data transmission is presented.

Synonyms

4G: Fourth generation; 4G/LTE technologies or 4G/LTE wireless networks; Advanced persistent threats(APT) or sophisticated attacks; LTE: Long-term evolution

Definitions

4G (Fourth Generation for wireless networks)

is a set of fourth-generation cellular data technologies, which enables multimedia communication and provides high data transfer rates.

LTE (Long-Term Evolution) denotes a standard for a smooth and efficient transition toward more advanced leading edge technologies for increasing the capacity and speed of wireless data networks.

TCP/IP (Transmission Control Protocol/Internet Protocol) refers to a set of protocols designed to construct a network of networks that a system uses for accessing the Internet/network.

APT (Advanced Persistent Threat) is a set of stealthy, advanced and continuous hacking processes, often launched and controlled by a hacker targeting a particular victim.

DoS (Denial of Service) is a cyberattack that attempts to disrupt services of a host or network.

Introduction

Over the last few decades, mobile systems have become essential for users to perform their daily tasks. This has led to the rapid evolution of wireless technologies, including the second generation (2G), third generation (3G), and fourth generation (4G) for mobile networks, to ubiquitously spread mobile telecommunication services (Seddigh et al. 2010). The 4G wireless technology has recently coined for improving broadband performance and allowing multimedia programs. Consequently, its architectures and standards have considerably enhanced to transfer higher data rates than 2G and 4G. Meanwhile, Long-Term Evolution (LTE) has evolved to become one of the effective technologies that accomplish the 4G wireless performance goals (Shaik et al. 2015).

Due to the high performances of 4G/LTE mobile devices, the LTE subscribers are expected to be about 3.16 billion by the end of 2018 (Statista 2018). There are various technological advances that 4G/LTE wireless networks provide when compared to earlier technologies. Firstly, 4G/LTE mobile systems work perfectly by utilizing the TCP/IP model. This, in fact, decreases financial and computational costs, where portable devices can connect to the Internet using an Internet Protocol (IP) without any constraints to previously closed cellular configurations. Nevertheless, with the wide variety of communication protocols included in the TCP/IP model, 4G/LTE wireless networks face multiple security and privacy issues (Seddigh et al. 2010; Shaik et al. 2015).

The key issues for securing 4G/LTE wireless networks can be summarized into three aspects. Firstly, mobile devices can flexibly access the Internet from any location and are therefore vulnerable to being hacked by different advanced persistent threats (APT). Secondly, while mobile IP-based systems are regularly updated with cryptographic and security mechanisms, there is an effect on their performance and traffic processing capacity that requires secure and upgraded wireless standards and architectures. Finally, although vendors are producing new generations of 4G/LTE technologies, they do not regularly develop new standards to mitigate vulnerabilities and deter growing cyber APT (Seddigh et al. 2010; Shaik et al. 2015; Li et al. 2018).

Background

This section discusses the background of 4G wireless standards and LTE architectures. Security controls of 4G/LTE architecture are also explained.

4G Wireless Standards

The International Telecommunications Union (ITU) declared an International Mobile Telecommunications-Advanced (IMT-Advanced) standard for 4G wireless networks. This standard

Security and Privacy in 4G/LTE Network, Table 1 Characteristics of 2G, 3G, and 4G technologies

Features	2G	3G	4G
Standards	GSM, iDEN,D-MPS	WCDMA, CDMA 2000	Single unified standard, ITU IMT-Advanced
Data rates	14.4 kbps	2 Mbps	100 Mbps
Services	Digital voice, Short Messaging	high-quality audio, video, data	Dynamic information access with higher multimedia quality, wearable devices
Technology	Digital cellular	Broad bandwidth CDMA, IP technology	Unified IP, seamless combination of broadband, LAN/WAN/PAN, WLAN
Core network	PSTN	Packet Network	Internet
Multiplexing	TDMA, CDMA	CDMA	CDMA

provides the specifications of radio access and core 4G wireless networks. The 4G wireless technology includes the following criteria: (1) high data rate, which is 100 Mbps for mobile devices and 1 Gbps for computer devices, (2) high quality of service (QoS) and capacity, and (3) high network speeds and coverage (Seddigh et al. 2010; Rao et al. 2017). The characteristics of 4G technologies compared with 2G and 3G are listed in Table 1 (Fagbohun 2014).

The bandwidth efficiency and allocation schemes are two important requirements that should be considered while designing 4G standards (Seddigh et al. 2010). In 4G wireless, voice/video multimedia is transited using the network protocols of the TCP/IP model. Therefore, the ITU-IMT-Advanced standard for 4G wireless technology should be configured to be compatible with the protocols and services of the TCP/IP model. Several 4G wireless standards, in particular, LTE and Mobile WiMAX, have been developed to meet the IMT-Advanced requirements and provide broadband wireless connections for mobile devices (Seddigh et al. 2010; Rao et al. 2017).

LTE Architecture

A LTE architecture includes the modules needed to install network protocols between base stations and mobile systems. As presented in Fig. 1, the architecture involves three modules: User Equipment (UE), Evolved Universal Terrestrial Radio Access Network (E-UTRAN), and Evolved Packet Core (EPC) (Seddigh et al. 2010; Shaik et al. 2015). The UE, for example, laptops

or smartphones, can link to the wireless network across the evolved NodeB (eNodeB) using the E-UTRAN base stations. The eNodeB utilizes some access network protocols for exchanging messages with the UE. The E-UTRAN links to the EPC which is an IP-based infrastructure, while the EPC links to the provider of the wireline IP network.

The 4G/LTE network architecture has some enhancements compared to 3G wireless (Shaik et al. 2015). Firstly, it has two types of network elements (NEs): (1) the eNodeB that is an improved base station and (2) the Access Gateway (AGW) that integrates all the functions, specifically Mobility Management Entity (MME), needed for the EPC. The MME can control the UE identification, as well as processing security authentication and mobility. LTE can support a meshed structure that improves wireless network performance, for example, an eNodeB can connect with several AGWs. Finally, as the architecture is compatible with the TCP/IP model, traffic packets at any UE can be handled using the AGW and eNodeB with different IP-based devices, such as routers.

4G/LTE Security Controls

Abstraction layers are inserted in the 4G/LTE architecture in terms of the unique identifiers (IDs) for smartphones (i.e., UEs). A temporary unique ID is used on the SIM card to prevent attackers from stealing identifiers. Another technique for improving 4G security is adding protected singling between the UE and MME (Seddigh et al. 2010; Mohapatra et al. 2015). Security

Security and Privacy in 4G/LTE Network, Fig. 1 LTE network architecture

mechanisms are utilized to secure the connections between 4G networks and secure non-4G networks using key management authentication protocols. Although several security controls are used for 4G/LTE wireless technology, its design, which is based on an open-IP architecture, and the sophistication of APT hackers make security and privacy of 4G/LTE systems challenging.

4G/LTE Security Requirements

In order to secure mobile devices that use 4G/LTE wireless technologies, there should be protection for the connections between the UEs and MMEs and between elements in the wireline networks and mobile stations. For satisfying these requirements, the 4G/LTE security is significantly improved by adding (1) advanced key hierarchy, (2) protracted authentication and key agreement, and (3) additional interworking security for the NEs (Mohapatra et al. 2015). The requirements are classified into key building blocks and LTE end-to-end security (Seddigh et al. 2010), as explained below.

- **Key building blocks** include the following elements:

- **Key security and hierarchy**

LTE has five key strategies used for connections of the EPS and E-UTRAN. The keys are declared as follows: (1) KANS encryption and integrity keys are used to protect non-access stratum (NAS)

traffic between the UE and MME, (2) a KUP encryption is used to encrypt traffic between the UE and eNodeB, and (3) KPRC encryption and integrity keys are used to secure the Radio Resource Control (RRC) between the UE and eNodeB.

- **Key management**

LTE key management comprises three functions: key establishment, distribution, and generation. It is essential that 4G/LTE wireless technology has key management mechanisms that prevent stealing keys, as mobile devices with IP-based infrastructure can frequently access different wireless networks. An Authentication and Key Agreement (AKA) process is utilized for establishing and verifying keys in 4G/LTE systems.

- **Authentication, encryption, and integrity protection**

LTE depends on using regular updating of the authentication process by exchanging sequence numbers in the messages of encryption mechanisms. The IPsec protocol and tunnels are also used for asserting the confidentiality of users' data while transmitting traffic between LTE nodes.

- **Unique user identifiers**

LTE has several user identifier mechanisms that thwart attackers from learning mobile user identities; therefore, attackers cannot track user profiles or launch denial of service (DoS) attacks against users. The identifier mechanisms

contain the following: (1) international mobile equipment identifier (IMEI) which is a permanent unique identifier for each mobile, (2) M-TMSI which is a temporary identifier that defines the UE inside the MME, and (3) cell radio network temporary identifier (C-RNTI) which is a unique and temporary UE identity when a UE is connected with a cell.

- **LTE end-to-end security** involves the following elements:

- **Authentication and Key Agreement (AKA)**

The foundation of LTE security is authenticating the UEs and wireless networks. This can be accomplished using the AKA process which asserts that the serving network authenticates the identity of a user and the UE certifies the network signature. The AKA creates encryption and integrity keys applied for originating various session keys for ensuring the 4G/LTE security and privacy.

- **Confidentiality and integrity of signaling**

Security of network access control planes is achieved when the RCC and NAS layer signaling is encrypted and integrity protected. Ciphering and integrity protection of LTE RRC signaling is executed at the packet data convergence protocol (PDCP) layer, whereas the NAS layer attains the protection by encrypting the NAS-level signaling. This protection cannot be uniquely performed for each UE connection, but it runs across trusted connections between AGW and eNodeB.

- **User plane confidentiality**

LTE has a security feature for user plane via encrypting data/voice between the UE and eNodeB. Encryption is executed at the IP layer by utilizing IPsec-based tunnels between AGW and eNodeB, but no integrity protection is offered for the user plane due to performance and efficiency considerations. The PDCP layer is used for enabling encrypting/decrypting the user

plane while transmitting traffic between the eNodeB and UE.

Cyberattacks and Countermeasure Techniques

4G/LTE wireless technology faces different types of cyberattacks that could affect integrity, privacy, availability, and authentication, as described below.

- **Privacy attacks**

Attacks against the privacy of mobile users' data attempt to expose sensitive data/multimedia of users. A man-in-the-middle (MITM) attack is the most serious privacy attacks in wireless networks that depend on a false base station attack when anomalous third-party masquerades its base transceiver station (Mohapatra et al. 2015). Privacy-preserving authentication and encryption mechanisms have been widely used to protect wireless networks against the MITM attacks (Ferrag et al. 2017; Deebak et al. 2016).

- **Integrity attacks**

Attacks against integrity attempt to modify exchanging data between the 4G access points and mobile users. Cloning attacks based on the MITM and message modification scenarios are the major integrity attacks that alter mobile user information. Authentication and privacy-preserving mechanisms with hash functions have been broadly used for securing 4G wireless networks against integrity attacks (Ferrag et al. 2017; Hasan et al. 2017).

- **Authentication attacks**

Attacks against authentication attempt to disturb the client-to-server and/or server-to-client authentication process. The password reuse, brute force, password stealing, and dictionary attacks are popular wireless hacking schemes that interrupt the password-based authentication. In the hacking schemes, an attacker can pretend to be a legal user

and try to log in to a server by guessing various words as a password from a dictionary. Encryption and authentication techniques have been utilized for preventing such kind of attacks from 4G wireless networks (Seddigh et al. 2010; Ferrag et al. 2017).

• **Availability attacks**

Attacks against availability try to make services unavailable, such as the service of data routing (Ferrag et al. 2017). The first in first out (FIFO) and DoS attacks can be launched by flooding massive malicious actions to 4G wireless victims for disrupting their computational resources. Firewall and intrusion detection systems have been usually used for defending against these attacks.

4G/LTE Challenges and Future Trends

Despite a plethora of research and technical studies that have been conducted for securing 4G/LTE wireless networks, there are several challenges that should be the focus of researchers in future that are discussed below, besides a summary in Table 2.

- Designing a flexible and scalable 4G/LTE architecture that can address security and privacy issues is an arduous task. There are multiple devices and systems that are usually

connected with 4G networks that result in vulnerabilities and loopholes in networks.

- Discovering DoS attacks that attempt to violate 4G wireless networks, as hackers frequently establish new sophisticated variants against eNodeB, UE, and discontinuous reception services.
- Location tracking denotes tracing the UE presence in a specific cell(s). While many portable devices could link to a 4G/LTE wireless network, ensuring that location tracks of the devices are not breached is still a challenging issue, due to the considerations of operability and scalability.
- The utilization of an effective 4G wireless Software Dened Network (SDN) is a challenge. More specifically, there are technical gaps in the network scalability, security, and privacy issues with the SDN.
- Trusted connections through 4G networks in the existence of eavesdroppers are the issues. Especially, when 4G wireless technology is used in the Internet of Things, it requires new cryptographic mechanisms that provide protection and integrity for smartphones and computer systems.
- Instead of individual security techniques, a systematic security and privacy protection strategies are required for 4G/LTE wireless connections while connecting with cloud and edge computing paradigms. This will provide

Security and Privacy in 4G/LTE Network, Table 2 Challenges and security and privacy methods of 4G/LTE technology

Challenges	Cyber-attacks	Security and privacy methods
A resilient 4G/LTE architecture	Privacy attacks: replay, MITM, impersonation, collaborated, tracing, spooing, privacy violation, masquerade	Privacy-preservation, authentication and encryption mechanisms
Tracking locations of devices	Integrity attacks: cloning, spam, message blocking, message modification attack, message, insertion, tampering	Hashing and encryption, and authentication and privacy-preserving methods
An effective 4G/LTE wireless Software Defined Network (SDN)	Availability attacks: FIFO, redirection, physical attack, skimming, and free-riding	Firewall systems, signature-based and anomaly-based systems
Collaborative 4G/LTE security and privacy approaches operate on cloud and edge paradigms	Authentication attacks: password reuse, password stealing, dictionary, brute force, desynchronization, forgery attack, collision, stolen smart card	Encryption and authentication techniques

valid security mechanisms, for example, trust models, device security, and data assurance techniques.

Key Applications

The 4G/LTE wireless technology has emerged for enhancing broadband performance and permitting multimedia applications. The technology has been used for the Internet of Things (IoT) for connecting Machine-to-Machine (M2M) systems and devices such as the In-Vehicle Multi-Carrier Router.

Definition

Authentication and access control policies to delay-/disruption-tolerant networks with limited bandwidth, relatively high bit error rates, and periods lacking connectivity interworking environment.

Historical Background

The history of delay-tolerant networking began as projects under United States government grants relating to the necessity of networking technologies that can sustain the significant delays and packet corruption of space travel. Initially, these projects looked only short-range communication between manned missions to the moon and back, but the field quickly expanded into an entire sub-field of DTNs that created the technological advances to allow for the Interplanetary Internet.

Introduction

The traditional transfer control protocol/Internet protocol (TCP/IP) plays an important role in

current Internet service (Akyildiz et al. 2004). Although not clearly stated, the existing Internet service is based on a number of key assumptions, such as an end-to-end link always exists between the source and its destination, the maximum round-trip time is not excessive, and the packet loss probability is small. However, a class of challenged networks would violate one or more of the assumptions, which will lead to this kind of network that may not be well served by the current end-to-end TCP/IP protocol. The architecture involved here is called delay-/disruption-tolerant networks (DTNs) (Fall 2003). The DTNs emerge in many circumstances, such as mobile ad hoc networks (MANET) (Zhang 2007), vehicle networks (VANET) (Pereira et al. 2012), satellite networks (Wang et al. 2013), etc. Different from the traditional network model, DTNs may have frequency disruption and long delay and no end-to-end link simultaneously, and the network model is constraint by limited storage/processing. As illustrated in Fig. 1, the DTN architecture includes the concepts of regions and DTN gateways (GWs). In Fig. 1, there are four network regions (A, B, C, D). Region B includes a DTN GW which locates on vehicles that cycle between DTN GW 2 and 3. Region D includes a low-

earth-orbiting (LEO) satellite link that also provides periodic connectivity (albeit perhaps more regular than the vehicle which may be subject to vehicular congestion or other delays).

The speciality of DTNs would result in TCP that cannot satisfy the applications over DTNs. To deal with the new challenges in DTNs, a new bundle protocol is overlaid on the transfer layer. As an “overlay” architecture, DTNs are intended to operate above the existing protocol stacks in various network architectures and provide a store-and-forward GW function between them when a node physically touches two or more dissimilar networks. For example, within the Internet, the overlay may operate over TCP/IP, and for delay-tolerant sensor/actuator networks, it may provide interconnection with some sensor transport protocol. Each of these networking environments has its own specialized protocol stacks and naming semantics developed for their particular application domain. Achieving interoperability between them is accomplished by special DTN GW located at their interconnection points. However, due to the speciality of DTNs, the security mechanism is different from that of traditional Internet networks. The main venue for DTN related security work is the Internet Research Task Forces (IRTF) (IRTF

Security in Delay-Tolerant Networks, Fig. 1 A typical DTN network architecture

2014) and Delay Tolerant Networking Research Group (DTNRG) (DTNRG 2009). The primary objective here is to overview those defining security services for DTNs.

Security in DTNs

In DTNs, the transmission media is usually oversubscribed and link capacity is a precious resource (Farrell et al. 2009). Thus, it is necessary to design some authentication and access control mechanism to protect the service of data forwarding, especially for the critical points in the network. Since there are multiple classes of services, the security mechanism considering endpoints is not very attractive. The reason is that end-to-end link mechanism requires some exchange of keys, which would be undesirable for high-delay and disconnection-prone networks. Moreover, it is undesirable to carry unwanted traffic all the way to its destination before an authentication and access control check is performed (Zhu et al. 2009).

Bundle Protocol Security

The unique data security in DTNs is focused on bundle layer, including faking bundle source, distorting the destination and control domain, modifying payload, etc. Such would consume the network resource and influence the confidentiality and reliability of payload in bundle layer. The regular way to solve the security of bundle protocol is encryption. However, due to the feature of DTNs, traditional encryption cannot apply, since it requires multiple interoperable and much resource consumption (Menesidou and Katos 2017).

To utilize the link resource and eliminate the large delay in DTNs, bundle protocol adopts opportunity routing to deliver data block. Different from that of the Internet, DTNs cannot authenticate the block in time, since there exists large delay, such that it is easily attacked by malicious nodes. Therefore, the bundle protocol needs to support a better block authentication.

Addressing security issues has been a major focus of the bundle protocol. Security concerns

for delay-tolerant networks vary depending on the environment and application, though authentication and privacy are often critical. These security guarantees are difficult to establish in a network without persistent connectivity because the network hinders complicated cryptographic protocols and key exchange, and each device must identify other intermittently visible devices. Solutions have typically been modified from mobile ad hoc network and distributed security research, such as the use of physical layer security.

Key Applications

The security of DTNs are involved in mobile ad hoc networks, vehicle networks (VANET), satellite networks, airborne networks, etc. Figure 1 illustrates a typical DTN, and there is an Internet connection available in a nearby town and a transport medium from the rural area to the town in the form of a vehicle, such as a bus or a car. There are two types of end users, mobile users, who use their own personal devices to connect directly to gateways. The bundle protocol security communication architecture targets mainly mobile users. Achieving security in such disconnected networks is a demanding task, but it is necessary in hostile environments with malicious attackers or even just passive listeners. In a hostile environment, secure DTN communication can provide an efficient way to let informers transfer information while hiding their identity from an enemy. Therefore, the utility of bundle protocol security in the DTNs is greatly expanded when the DTNs provide end-to-end security.

Definition

A sharing economy is an economic model in which individuals (businesses or consumers) are able to borrow or rent assets owned by others. This model is usually successful when the price of a particular asset is high, and it is not fully utilized by its owner. Collaborative consumption is an example of a sharing economy in which there is shared use of assets or services by a group. It differs from standard commercial consumption in that the cost of purchasing the assets or services is not borne by one individual but instead is divided across a larger group, with the asset costs usually being recovered through renting or exchanging. In communication networks economic models of sharing are being used to share expensive infrastructure among network operators or to create a whole access network via individuals' Wi-Fi sharing.

A key idea behind such sharing models is the paradigm shift away from the exclusive ownership and use of assets or resources to one of shared use. Value is derived from the fact that most assets are acquired to satisfy peak demand but are otherwise poorly utilized. So sharing has the benefit of increasing access to resources while reducing investments in assets. This movement takes advantage of innovative new ways

of peer-to-peer (P2P) sharing that are voluntary and enabled by Internet-based exchange markets and mediation platforms. Several successful businesses like Uber and Airbnb in the USA and elsewhere provide a proof-of-concept and evidence for the viability of the sharing economy.

A key ingredient of a P2P sharing economy application is the Internet-based platform that implements the underlying economic model. Its success depends on reducing the various transaction costs, creating not just a marketplace but also a market for the given service, and becoming a trusted third party that enforces the rules of the service and checks for quality.

In the case of telecom services, one can broadly distinguish two types of sharing models. The first type is a business-to-business (B2B) case, where basic network infrastructure is shared among competing providers in order to minimize their costs. The economic drive is to achieve large economies of scale. The second type concerns P2P sharing where the network infrastructure and the corresponding service is provided by individuals instead of companies, as in the case of Wi-Fi sharing to produce ubiquitous Internet access. In this case the success of the model depends on the large positive externalities of offering network access as a public good.

Historical Background

The Case of B2B

The telecommunication industry enjoys large economies of scale, and it is typical that telecom operators must make considerable investment in technology and infrastructure and upgrade this every few years. Consequently, infrastructure sharing, as it limits duplication, is becoming a successful business paradigm in the industry. In many cases competitors are becoming partners in order to lower their continuing investments and the new technology upgrades. The degree and method of infrastructure sharing vary in different countries depending on regulatory and competitive conditions. From the market efficiency point of view, infrastructure sharing can significantly facilitate entry for new players

by decreasing the level of required investments, with great impact on competition. The market becomes more attractive to new players, with a lower barrier to entry and reduced business risk. Infrastructure sharing allows operators to focus more upon improved innovation and better commercial offerings, increasing consumer surplus (see OECD 2015).

There are two basic categories of sharing mobile infrastructure: passive and active. Passive sharing refers to the sharing of physical space (i.e., in buildings, sites, and masts) where networks remain separate and run their own equipment. In active sharing, active elements of a mobile network are shared, such as antennas, entire base stations, or even functions of the core network. A popular form of active sharing is mobile roaming. An operator uses the infrastructure of another network in geographic areas where it has no infrastructure of its own.

However, the decisions faced by mobile network operators on which resources they might share, and how they should compete with operators with whom they do share facilities, are subtle and might depend on the type of contracts that will be in place. There is always the risk of a competitor that shares infrastructure to learn strategic information like traffic density, network load, etc. Also sharing might impact an operator's capability for competitive differentiation, its freedom in making decisions for new technology investments, and its operational practices. Regulators may be concerned that network sharing may have negative impact upon competition. Two or more operators could share resources in such a way creating anti-competitive discrimination against other operators.

The Case of P2P

Wi-Fi signals of access points (APs) set up by individuals for their own use already pervade many cities, and all together cover a significant fraction of the city's geographical area. In most cases such a network cell installed by its owner covers a greater area than originally intended and hence is accessible to other individuals that are nearby. Given how easy it is to gain access to an AP once a potential user is within its

coverage area, and leaving aside the obvious security issues involved, it is sensible that individuals could share such infrastructure among themselves to achieve ubiquitous Internet access. Sharing comes as a natural idea since Wi-Fi technology provides large amounts of bandwidth that is mostly underutilized by its original user both at the access level and also at the backhaul. So the important questions are (i) How does a “primary” user gain by sharing her AP with other “secondary” users and (ii) make sure that she does not lose by doing so (decrease of network speed, security risks).

The key idea is to offer the right incentives to individuals to share their owned private Wi-Fi APs with each other, i.e., to crowdsource the public network coverage of large geographic areas using private APs. Users can benefit from joining such a community network by using other users APs when traveling to the corresponding locations. Clearly, the success of such a crowdsourcing model largely depends on the degree of participation and contribution of many individual Wi-Fi owners and requires a careful design of the economic incentives. Key issues for success are (i) the ability of the local AP to isolate secondary user traffic from primary user traffic for performance and security reasons, (ii) the distributed management of such a large infrastructure, (iii) the size of the anticipated network since a larger network is more useful to its users, and (iv) pricing and economic incentives in general. It should be stressed that although technology can solve the first two, pricing is rather open and can lead to different business models. For example, the platform could operate in a tit-for-tat fashion, blocking users whose AP is turned off to secondary users. Or subsidize users for the cost of the new AP equipment or for part of their broadband connection to the ISP. Profits could be made by charging users from other communities that like to use the platform or from mobile network operators (MNOs) by allowing them to offload data of their customers.

A prominent example of a commercial wireless community networks is Fon (see [FON web-site](#)) which has more than 20 million member Wi-Fi APs around the world. The original idea was to

create an ubiquitous network for Wi-Fi access for its customers. To become a Fon member, users had to buy a special router called a “Fonera.” With this router, they agreed to share part of their bandwidth as a second Wi-Fi signal, in exchange for the right to use other members’ Fon APs. More precisely, the operator incentivizes Wi-Fi sharing using two incentive schemes corresponding to two types of membership: as a “Linus,” a user can get free Wi-Fi access within the community network coverage by sharing her Wi-Fi for free, and as a “Bill” a user can earn an additional fraction of the revenue generated from roaming traffic after subtracting certain costs. As an “Alien” a user who does not own a Wi-Fi AP can still access the Fon network by purchasing Wi-Fi passes from the operator.

Foundation

Underlying the B2B and the P2P sharing models are some basic economic models.

In the B2B model, partnering businesses jointly pay for a common infrastructure, which is useful to them all, but not necessarily to the same extent. If all partners are given equal access and are expected to share equally the cost, then the amounts that partners are willing to contribute to such cost can be less than optimum and lead to a “poor infrastructure” system and also free-riding by partners who ought to be paying more. Free-riding takes can place when a participant can use infrastructure built by others while contributing very little to its total cost. When all participants expect to be able to free-ride then a socially inefficient choice of poor infrastructure system can occur.

A way to remedy that is to request participants to contribute some minimum amount or incentivize them to contribute more by differentiating the quality of service obtained by using the infrastructure, i.e., by relating the amount of cost that a partner bears to priorities in accessing the infrastructure, etc. These issues are illustrated in the following simple model of economic agents that build a common infrastructure and derive benefit from its usage.

Suppose that a shared infrastructure is to be built, of quality or quantity Q . This can be modelled as a public good since its larger size benefits all agents that have access to it. The social welfare obtained by a population of n agents is then

$$\sum_{i=1}^n \theta_i u(Q) - c(Q).$$

Here u is an increasing concave function assumed known, and θ_i is a parameter which expresses the importance that agent i attaches to using the system. The optimal choice of Q will depend on all the values of the $\theta_1, \dots, \theta_n$, which are the private information of the agents: i.e., θ_i is known only to agent i , though its a priori distribution is known. One must ask agents to reveal their θ_i and then choose Q and impose agent-specific payments, each of which depends on all of $\theta_1, \dots, \theta_n$. These payments should cover the cost $c(Q)$. However, the agents, knowing how the above will be done, may act strategically, i.e., agent i may choose to declare a non-truthful value $\hat{\theta}_i \ll \theta_i$ in order to be charged a smaller fraction of the total cost. In doing so she assumes that all other agents j will declare their true values of θ_j , and hence the system will be built at a large scale, not being much influenced by her non-truthful declaration. Note that this strategy makes more sense as the number of participants gets larger. If all agents declare small $\hat{\theta}_i$ s, the corresponding optimal choice of Q will also be small.

The so-called mechanism design problem is to devise rules that will obtain the best outcome subject to agents acting strategically. When n is small, this is exceedingly difficult. However, as described in Courcoubetis and Weber (2012), there is, when n is large, a nearly optimal design in which, by knowing only n and the expected average of the θ_i 's, one can set $Q = Q^*$ and impose on each agent the same fixed fee p for participation. Agent's will self-select: i.e., agent i chooses to participate only if $\theta_i u(Q^*) - p > 0$. By extending this simple model, one can further investigate the effect of offering differentiated quality of service in proportion to the cost covered by each agent.

In P2P, agents contribute in kind. Each agent benefits from the contribution of others resources but pays only the cost of its own contribution. Consider, for example, a population of agents; suppose agent j_i makes available some shared Wi-Fi service which other agents can connect to and use when roaming in her locale j . She provides this "connectivity service" in quality Q_{j_i} (such as availability or download speed). The total available for the community in locale j is $Q_j = Q_{j_1} + \dots + Q_{j_{n_j}}$, summed over the n_j agents who provide shared Wi-Fi in locale j (though as concerns agent j_i , this should omit her own contribution Q_{j_i} to the community Q_j , for while she benefits from the contributions of other agents in locale j she has anyway Wi-Fi connectivity in her own premises.) Agent j_i incurs a cost in providing Q_{j_i} which is a function of both Q_{j_i} and the load the other agents place on her networking equipment, say $c(Q_{j_i}, \cdot)$. By using the Wi-Fi of others, agent j_i obtains for herself net benefit of the form

$$\theta_{j_i} \sum_{k=1}^L u(Q_k) - c(Q_{j_i}, \cdot), \quad (1)$$

where $\theta_{j_i} u(Q_k)$ measures the utility she receives due to roaming in locale k . Suppose the form of u is known and the same for all agents and locales, but θ_{j_i} is information private to agent j_i . Now there can be a free-rider problem, in that the user j_i might do best for herself by setting $Q_{j_i} = 0$. Of course there is an easy remedy: simply require her to provide Wi-Fi of at least some specified amount $Q_{j_i}^*$, or otherwise she is barred from sharing the wireless of others when she roams.

When the aim is to maximize total social welfare (which is the sum of (1) taken over all agents), then optimal values of the $Q_{j_i}^*$ will depend on the values of all the θ_{j_i} , which we have assumed are not known to the system designer. However, when the total number of agents is large, a scheme can be designed in which each agent in locale j is asked to contribute some minimum quality $\bar{Q}_j$. This will obtain nearly the same optimum social welfare as when all θ_i are known and appropriate optimal $Q_{j_i}^*$ are required of the agents. Some agents, who know their θ_{j_i}

to be small, will choose not to participate in such a system. But those who do participate will not be free-riding, and the system will dimension to the optimal scale (see Courcoubetis and Weber 2004). Similar models have been analyzed in Manshaei et al. (2008), Afrasiabi and Guerin (2012) and Ma et al. (2017).

Sidelink Transmissions and Proximity Services in LTE-A and Beyond

Shao-Yu Lien¹ and Der-Jiunn Deng²

²Department of Computer Science and Information Engineering, National Changhua University of Education, Changhua City, Taiwan

Synonyms

[Device-to-device \(D2D\) communications](#); [Direct transmissions](#)

Definition

Sidelink in LTE-A denotes a transmission direction from a user equipment (UE) to another UE(s), in contrast to downlink from an eNB to a UE and uplink from a UE to an eNB. In sidelink transmissions, if a UE has data to be transmitted to another UE(s), a UE can directly transmit data to the destination UE without signal relay via an eNB. Consequently, sidelink transmissions can only take place among two or more UEs within the signal coverage of each other, and such a framework is also known as proximity services (ProSe) or direct transmissions.

Historical Background

Since 2012, the First Responder Network Authority (FirstNet) of the United States (US) Department of Commerce (DoC) is tasked with creating a nationwide network to provide wireless services for public safety agencies across the United States. However, as the costs to develop and to maintain a mobile network particularly for public safety are drastically increasing, this obstacle consequently drives the exploitation of existing telecommunication infrastructures. Considering the economic scale of LTE/LTE-A and the capabilities to provide multi-megabit per second data rates, 3GPP Release 12 is thus endorsed as the next-generation nationwide public safety network in the United States. Using dedicated 700 MHz spectrum allocated by the Federal Communications Commission (FCC), emergency responders such as police, fire brigade, and ambulance are able to receive immediate wireless services when public safety events (such as rescue, conflagration, riot, accident, etc.) occur. However, although most requirements for public safety can be supported by LTE/LTE-A Ferrus et al. (2013), there is a critical concern. When a part of or all eNBs are unavailable due to natural disasters or malicious attacks, wireless services still need to be provided at least locally for a group of users. For this particular requirement needing to be supported by a public safety network, two key technologies are supported by 3GPP Release 12: D2D proximity services (ProSe) and group communications (3GPP TR 36.843 V12.0.0 2014; Lien et al. 2016a).

Enabling UEs to directly exchange data without signal relays via eNBs, D2D communications have been well studied in the literature to provide considerable benefits, including significant improvements in spectrum (reuse) efficiency (Yu et al. 2011; Peng et al. 2014), transmission data rate using higher-order modulation and coding schemes (MCSs), power saving, and latency performance (Liu et al. 2015; Peng et al. 2014). With sufficient analytical foundations, the potentials of D2D communications are fully approved. However, achieving above engineering merits is not the primary design goal of D2D ProSe in

Release 12. Instead, a new feature of supporting communications with or without coordination from the network is created, which leads to two components in Release 12 D2D ProSe. (i) Through network-assisted discovery, UEs in close physical proximity are able to discover the existence of each other. (ii) Direct communications among two UEs are able to take place with or without supervision from the network (Wu et al. 2016). This feature saves scarce resources of the network for data exchanges when public safety events occur and empowers local communications among UEs outside network coverage. On the other hand, many public safety applications may require communications among a group of users. For example, users in a police team or a fire brigade team may share messages/voice with all other members in the team. For such a case, group communications are thus a technology to enable one-to-many communications.

To further extend the UE-to-network relay in Release 13, many countries adopting Release 12 as their public safety networks also decide to maintain PC5 interface unchanged (which will be elaborated later). In this case, only Layer 1 and Layer 2 of PC5 are insufficient to support the UE-to-Network relay, and additional procedures on the top of Layer 1 and Layer 2 (i.e., in Layer 3) should be needed to exploit Layer 1 and Layer 2. As a result, the UE-to-network relay in Release 13 is a Layer 3-based relay.

In Release 12, solely the D2D discovery for the in-coverage scenario and D2D broadcasting communications are solely supported. However, for public safety, an in-coverage UE may frequently move outward and toward eNB coverage, and therefore providing service continuity for D2D ProSe is of crucial importance. Fundamentally based on Release 12, the capabilities of discovery and communications in Release 13 are extended to support the partial-coverage and the out-of-coverage scenarios. Particularly for the transition from the in-coverage scenario to the partial-coverage scenario, an in-coverage UE is able to facilitate communications between an eNB and an out-of-coverage UE. For this

purpose, this feature is known as the Layer 3-based UE-to-network relay (Lien et al. 2016b).

Foundations

Since the major purposes of Release 12 D2D ProSe are to share the traffic load of the network when a large amount of data exchanges are needed in public safety events and to enable local voice/data communications when a part of or all eNBs are unavailable, three scenarios are supported by Release 12 and Release 13 D2D ProSe, as shown in Fig. 1:

- **In-coverage** This scenario indicates that all the considered UEs are within eNB coverage (in-coverage UEs) to receive services/signals from an eNB.
- **Out-of-coverage** This scenario indicates that all the considered UEs are outside eNB coverage (out-of-coverage UEs) and cannot receive services/signals from an eNB.
- **Partial-coverage** This scenario indicates that some UEs are within eNB coverage, while other UEs are outside eNB coverage.

To support these scenarios, a new air interface known as PC5 is provided in addition to the conventional Uu interface. Different from Uu (defining the link between an eNB and a UE (to support downlink or uplink transmissions)), PC5 is the interface between two UEs (to support **sidelink** transmissions, in contrast to uplink and downlink), as shown in Fig. 1. In Release 12, PC5

is a connectionless interface. Unlike Uu in which a receiver is able to report messages back to a transmitter (these messages include channel state information, precoding matrix index, rank index, acknowledgment, or negative acknowledgment), feedback channels are not supported over PC5. In Layer 1, PC5 reuses the radio resources on the physical uplink shared channel (PUSCH) of Uu based on a twofold reason. Firstly, in the PUSCH, transmitters are UEs and the receiver is an eNB. When a UE is uploading data to an eNB, other UEs are able to perform D2D ProSe concurrently if the interference from a D2D link to the eNB is limited. However, in the physical downlink shared channel (PDSCH), a common transmitter is an eNB. In this case, if two UEs perform D2D communications concurrently along with a downlink transmission, the eNB becomes a strong interference source. Therefore, operating PC5 at the PUSCH reaches a higher spectrum efficiency. Secondly, the single-carrier frequency-division multiple access (SC-FDMA) is adopted for the PUSCH in LTE/LTE-A, while the orthogonal frequency-division multiple access (OFDMA) is adopted for the PDSCH. Considering that the peak-to-average power ratio (PAPR) in the SC-FDMA is smaller than that in the OFDMA, operating PC5 at the PUSCH also reaches a higher energy efficiency.

In PC5, there are two modes of resource allocations:

- **Mode 1** An eNB schedules radio resources for a UE to transmit direct data and control information for D2D communications.

Sidelink Transmissions and Proximity Services in LTE-A and Beyond, Fig. 1 Release 12 D2D ProSe support three scenarios: in-coverage, out-of-coverage, and partial-coverage

- **Mode 2** A UE on its own “randomly” selects resources from the pre-configured resource pools to transmit direct data and control information for D2D ProSe.

The Mode 1 resource allocation is supported by in-coverage UEs, while the Mode 2 resource allocation can be supported by both in-coverage and out-of-coverage UEs. If an in-coverage UE supports the Mode 2 resource allocation, the resource pools for this UE may be configured by eNBs. When a transmitter UE determines the radio resource occupation for D2D ProSe (either scheduled by the eNB or randomly selected by the UE), the transmitter UE needs to inform the receiver UE about its radio resource occupation. This information is referred to as sidelink control information (SCI). The radio resources used to transmit SCI also follow the Mode 1 and Mode 2 allocations. In other words, before data transmissions, a transmitter UE needs to decide the radio resources for transmitting SCI (either scheduled by the eNB or randomly selected by the UE). However, this radio resource occupation for SCI is unknown by a receiver UE. Therefore, a receiver UE needs to perform blind detection of radio resources carrying SCI.

In PC5, the following sidelink physical signals and channels are supported, and the time-frequency resource locations of these sidelink physical signals/channels are illustrated in Fig. 2a:

- **Sidelink Synchronization Signals (SLSSs)** In LTE/LTE-A, synchronous operations are adopted. That is, all eNBs and all UEs should follow the same timing reference. To achieve this goal, in Uu, each eNB should broadcast the primary and secondary synchronization signals (carrying the timing reference) for all UEs to synchronize to. However, in the partial-coverage and out-of-coverage scenarios, there are UEs outside eNB coverage. Thus, only eNBs broadcasting synchronization signals are not enough. To enable all eNBs and all UEs (including in-coverage UEs and outside coverage UEs) following the same

timing reference, in the partial-coverage scenario, an in-coverage UE can transmit its timing reference for outside coverage UEs to synchronize to. In the out-of-coverage scenario, an outside coverage UE is also able to transmit its timing reference for other outside coverage UEs to synchronize to. An eNB or a UE transmitting its timing reference is referred to as a **D2D synchronization source**. Therefore, there can be multiple collocated D2D synchronization sources. The transmitted signals carrying the timing reference are thus referred to as the SLSSs. By this definition, an eNB is certainly a D2D synchronization source, and the corresponding SLSSs are the Release 8 primary and secondary synchronization signals. In Release 12, there are two types of SLSSs: primary SLSS (PSSS) and secondary SLSS (SSSS).

- **Physical Sidelink Broadcast Channel (PSBCH)** In addition to the SLSSs, a D2D synchronization source also transmits the PSBCH, which carries information to support D2D synchronization, such as the frame number on the sidelink, the system bandwidth, the ID of the synchronization source, the type of synchronization source (i.e., the timing reference is derived by a UE or an eNB), the time division duplex (TDD) or frequency division duplex (FDD) configuration, and the stratum level (see Lien et al. (2016a) for the D2D synchronization procedure).
- **Discovery Signal and Physical Sidelink Discovery Channel (PSDCH)** The purpose of D2D discovery is to identify the existence of neighboring UEs. In Release 12, D2D discovery is only supported in the in-coverage scenario, and D2D discovery and D2D communications are two independent procedures. In other words, facilitating D2D communications is not the sole goal of D2D discovery, which also facilitates other public safety tasks. On the other hand, D2D communications are able to take place even without D2D discovery (without knowing the existence of neighboring UEs) through broadcasting. In Layer 1, two UEs discover each other via exchanging the discovery signals through the PSDCH

a

b

Sidelink Transmissions and Proximity Services in LTE-A and Beyond, Fig. 2 (a) Time-frequency resource locations of sidelink physical channels. (b) Layer 3-based UE-to-network relay in enhanced D2D ProSe

within a discovery period. During each discovery period, two types of D2D discovery are supposed:

- **Type 1:** Radio resources for discovery signal transmissions are allocated on a non-UE-specific basis. That is, the allocated

radio resources can be used by all UEs to transmit their discovery signals.

- **Type 2:** Radio resources for discovery signal transmissions are allocated on a per-UE-specific basis. That is, the allocated radio resources are only utilized by a specific UE to transmit the discovery signal:

Type 2A: Radio resources are allocated at each discovery signal transmission time instant.

Type 2B: Radio resources are semi-persistently allocated for discovery signal transmissions.

For the Type 1 discovery, the radio resources for transmitting the discovery signals can be shared by multiple UEs, and therefore this type of discovery can be supported by in-coverage UEs or UEs outside coverage. However, for the Type 2 discovery, the radio resources are allocated to each particular UE, and therefore this type of discovery is supported by in-coverage UEs, by which the radio resources are scheduled by an eNB. The PSDCH carries physical discovery signals which map the application layer discovery messages to physical signals for discovery (see a complete D2D discovery procedure from the application layers to Layer 1 in Lien et al. 2016a).

- **Physical Sidelink Control Channel (PSCCH) and Physical Sidelink Shared Channel (PSSCH)** Similar to the PUCCH and PUSCH used for uplink control and data transmissions, respectively, the PSCCH and PSSCH are used for Layer 1 control and data transmissions in D2D ProSe. The PSSCH carries data transmissions (e.g., voice) from upper layers via a unicast bearer or a multimedia broadcast multicast service (MBMS) bearer (as discussed later). On the PSCCH, a D2D transmitter can transmit SCI format 0, which carries the MCS used for D2D communications, the frequency-hopping flag to indicate whether to activate frequency hopping in D2D communications, the RB assignment and hopping resource allocation to indicate the RB allocation, T-RPT as aforementioned, and the timing

advance (TA) to indicate the timing difference between the downlink timing and the uplink timing. Please note that, in the conventional LTE/LTE-A Uu interface, eNBs broadcast synchronization signals in the downlink frequency band (for the FDD mode). By receiving these synchronization signals, each UE is able to synchronize to an eNB in the downlink frequency band. However, the timing reference of a UE does not align with the timing reference of an eNB in the uplink frequency band. To schedule an uplink transmission in uplink channels, an eNB thus should provide information of TA to inform a UE about the timing difference between the downlink frequency band and the uplink frequency band. Similarly, for D2D ProSe, an in-coverage UE should synchronize to an eNB in the downlink frequency band. However, sidelink channels reuse the frequency bands of uplink channels. Although SLSSs can be transmitted over the sidelink to facilitate synchronizations in the partial-coverage and out-of-coverage scenarios, TA to indicate the timing difference between the downlink channels and sidelink channels is still necessary, particularly in the partial-coverage scenario. Similar to the Uu interface that TA is carried by the control channel, TA in sidelink is also carried in the PSCCH.

Since sidelink signals/channels reuse the same radio resources of the PUSCH, it is possible that sidelink signals/channels utilize the radio resources those have been occupied by channels/signals on the PUSCH. In this case, the PUSCH has a higher priority to utilize the radio resources. It is also possible that multiple sidelink signals/channels may occupy the same radio resources, and the SLSSs/PSBCHs have the highest priority among other sidelink signals/channels.

In the partial-coverage and the out-of-coverage scenarios, out-of-coverage UEs may not receive control signals from an eNB. In this case, unlike the in-coverage scenario where radio resources for D2D discovery are

scheduled by an eNB (through the Type 2 discovery), radio resources of UEs outside coverage may not be fully controlled by an eNB. Consequently, the Type 1 discovery is primitively employed to the partial-coverage and the out-of-coverage scenarios. Similarly, unlike the in-coverage scenario where the timing reference for synchronization is provided by an eNB, UEs outside coverage may not receive the primary/secondary synchronization signals from an eNB. Losing synchronization, D2D discovery may not be successfully performed at an outside coverage UE. To facilitate synchronization for D2D discovery in the partial-coverage and the out-of-coverage scenarios, the following two behaviors to transmit SLSSs are supported in Release 13:

- **Behavior 1** A UE in each discovery period reuses the procedure of SLSS transmissions in Release 12.
- **Behavior 2** A UE in each discovery period (in which UE transmits discovery signals) transmits SLSSs every 40 ms.

In Release 12, the purpose of D2D discovery is solely for public safety, while in Release 13, the purposes of D2D discovery in the in-coverage scenario can be extended to nonpublic safety (e.g., commercial purposes). For an out-of-coverage UE transmitting the discovery signals using the Type 1 discovery, it should transmit the SLSSs following the Behavior 2. On the other hand, for an in-coverage UE transmitting the discovery signals using the Type 1 discovery, it should transmit the SLSSs following the Behavior 1 for a nonpublic safety purpose, and an eNB is able to configure to adopt the Behavior 1 or the Behavior 2 for public safety.

To initiate a relay discovery, an eNB should broadcast information associated with the relay discovery, to indicate that the relay discovery can be currently supported. In addition to the broadcast signaling, an eNB may also announce the transmission resource pool(s) and/or reception resource pool(s) for the relay discovery. Such a broadcast signaling may directly activate an in-coverage UE to be a relay

(UE) for the relay discovery, even though this in-coverage UE is in the idle mode. Through the broadcast signaling, an eNB may indicate the minimum and/or the maximum Uu link quality thresholds, by which a relay UE is able to autonomously start/stop the relay discovery. Nevertheless, if an in-coverage UE only receives the broadcast signaling from an eNB while the transmission resource pool(s) is not received, then an in-coverage UE is able to initiate a request for the relay discovery. Upon receiving such a request, an eNB may send the “dedicated signaling” to configure the UE (should be in the connected mode) to be a relay.

As aforementioned, due to mobility, an in-coverage UE may frequently move toward/outward coverage of an eNB. To provide the service continuity and extend the service range of an eNB, an in-coverage UE may be selected as a relay UE to relay data between an eNB and a remote UE, as shown in Fig. 2b. The procedure to select an appropriate relay UE is known as the relay selection. Due to fading channels and mobility, a selected relay UE may not always be suitable for the data relay all the time. When a relay UE is no longer suitable to support signal relay, a new relay UE may need to be selected, and this procedure is known as the relay reselection.

To select/reselect an appropriate relay UE, the link quality (e.g., reference signal receiving power, RSRP) both in PC5 and in Uu should be taken into consideration. Since a relay UE is generally in-coverage while a remote UE could be outside coverage, the link quality in PC5 may induce a larger impact than that in Uu to the performance in UE-to-network relay. To quickly adapt to the channel variation in PC5, a remote UE is able to trigger relay reselection.

Key Applications

Push-to-talk (PTT) services are major applications being supported by D2D ProSe, which provide a method for two or more users to engage in voice communications. Using PTT services, users request to transmit by means of

pressing a button on a UE. Therefore, each UE may autonomously initiate a voice transmission. The MCPTT is an enhancement of PTT services suitable for mission-critical scenarios based upon 3GPP evolved packet system (EPS) services. The MCPTT service is intended to support voice/audio communications among several users (i.e., group communications), where each user has the ability to gain access to the permission to talk in an autonomous manner. The normal operation in group communications is that one user in a group is allowed to talk at a time, to avoid interference in a group. The MCPTT thus further provides mechanisms to arbitrate among multiple transmission requests in contention. These mechanisms are also known as the floor control and priority control. In other words, when multiple requests occur, the determination of which user's request is accepted and which users' requests are rejected/queued is based upon the respective priorities in contention. For example, a team leader of a police group communicating with a sniper on the roof needs to give a "shoot" or "do not shoot" voice message in time. This request may be associated with a high priority.

Distinguishing priorities among transmitted traffic from a single user and from multiple users is of crucial importance for a public safety network. When a user presses the button to transmit an urgent voice message, a public safety network does not have to wait for transmission termination of currently ongoing traffic with a lower priority. Instead, a public safety network shall suspend the ongoing transmissions immediately and shall yield the radio resources to support the urgent message (with a higher priority). This operation is known as preemption or interruption. In D2D ProSe, the granularity to assign priorities to traffic from users is a packet (i.e., D2D ProSe support per packet priority, PPP). Since the Internet Protocol (IP) is supported by LTE-A, the definition of a packet in the priority control and floor control mechanisms is an IP packet.

In conventional mobile networks, a class of schemes to properly arrange transmissions of different traffic flows according to the corresponding priorities are known as floor control. These

schemes include first-come-first-served (FCFS), token passing, round robin, etc. Floor control is also capable to limit the time of a user's talk (hold the floor), which thus permits requests of the same or lower priorities a chance to regain the floor. Floor control can be implemented in the application layer and therefore imposes no impact to the lower layer designs. However, as an MCPTT packet of a higher priority attempts to be transmitted, it is a challenge to interrupt the ongoing MCPTT transmission of a lower priority and release the radio resources immediately at lower layers. As a result, solely using floor control in the application layer, the latency performance to serve an urgent packet transmission may be a critical concern.

In lower layers, practicing transmission interruption is also a very challenging issue. For Mode 1 resource allocations, since an eNB schedules radio resources for all UEs, radio resource allocations for packets of different priorities can be fully controlled by an eNB. For Mode 2 resource allocations, each UE autonomously accesses radio resources. Due to the nature of a half-duplexing radio, when a UE is transmitting a low-priority packet, it may not receive a request of a high-priority packet transmission. As a result, a high-priority packet transmission still has to wait for a low-priority packet transmission.

To provide sufficient opportunities for a high-priority packet transmission particularly in Mode 2 resource allocations, Layer 2 of D2D ProSe supports a configurable mapping of PPP levels to different Mode 2 resource pools. In other words, there is a one-to-one mapping to associate each PPP level with a resource pool(s). As a result, when a high-priority packet needs to be transmitted, a resource pool(s) is reserved such that the packet can be transmitted immediately.

Future Directions

3GPP vehicle-to-everything (V2X) radio access aims at enabling a vehicle to exchange data with other vehicles (vehicle-to-vehicle, V2V), pedestrians (vehicle-to-pedestrians, V2P), and infras-

Sidelink Transmissions and Proximity Services in LTE-A and Beyond, Fig. 3 3GPP V2X includes V2V, V2P, and V2I. Through reusing PC5 interface design-

ated for direct UE communications, in-coverage, out-of-coverage, and partial-coverage scenarios can be supported

structure (vehicle-to-infrastructure, V2I), where infrastructure can be an eNB-type RSU or a user equipment (UE)-type RSU. The supported scenarios in V2X taxonomy are illustrated in Fig. 3. In V2I, if infrastructure is an eNB-type RSU, then Uu interface is reused. In V2V, V2P, and V2I (in the case that infrastructure is a UE-type RSU), PC5 is utilized.

On Uu, radio resources for uplink/downlink transmissions are allocated/scheduled by an eNB. However, for PC5, there are two radio resource allocation schemes (i.e., Mode 3 and Mode 4) depending on the following deployment scenarios. Please note that Mode 1 and Mode 2 are used for Release 12 and 13 D2D:

- **In-coverage** In this scenario, all vehicles/pedestrians are under coverage of an eNB, and both of the following two resource access modes can be adopted. (1) Radio resources used for sidelink transmissions are scheduled by the eNB, which is known as Mode 3. (2) Each vehicle/pedestrian on its own randomly selects radio resources from the pre-configured resource pool(s) to perform sidelink transmissions, which is known as Mode 4.
- **Out-of-coverage** In this scenario, all vehicles/pedestrians are out of eNB's coverage, and only Mode 4 is supported as there is no eNB able to perform resource scheduling.

- **Partial-coverage** In this scenario, a part of vehicles/pedestrians are in-coverage, while other parts of vehicles/pedestrians are out-of-coverage. Both Mode 3 and Mode 4 can be applied to this scenario.

Since there is no resource coordination among UEs in Mode 4, multiple transmitter UEs may select the same radio resource(s) as their PSCCHs. In this case, these PSCCHs collide with each other, and receiver UEs may lose the following PSSCHs. To mitigate PSCCH collisions, an enhancement of Mode 4 is provided in 3GPP Release 14 V2V. When a transmitter vehicle attempts to launch a transmission burst, it senses the resources in a measurement window and only selects resources not being occupied by other transmitters to transmit PSCCH. Nevertheless, as the resources carrying PSSCH are also randomly selected by each transmitter, it is still possible that there is no collision among PSCCHs, while collisions may occur among PSSCHs from different transmitters (Lien et al. 2017).

In Release 12 and 13 PC5, PSCCH and PSSCH are multiplexed in the time domain. However, to reduce radio access latency in V2V, PSCCH and PSSCH are multiplexed in the frequency domain. In this case, a receiver needs to receive signals over all resources within a particular time window (i.e., PSCCH/PSSCH transmission window), blindly detect corresponding PSCCH, and retrieve data at PSSCH. This design may not be cost-efficient in terms of complexity and energy, as the “space” for blind detection is largely extended. Nevertheless, complexity and energy may not be issues for a vehicle in practice. This design further enhances reliability in data reception, as a receiver receives signals within a PSCCH/PSSCH transmission window, rather than randomly selecting some resources to perform detection.

[Situational awareness](#)

Introduction

Situation awareness (SA), which was first clearly proposed by [Endsley](#) in (1988), has attracted the interest of practitioners and researchers in a variety of domains, including aviation, air traffic control, ship navigation, health care, military command and control operation, and environment ([Endsley 1995](#)). The early research on SA mainly took place in the aviation and military domains ([Parasuraman et al. 1992](#)). In order to conduct SA-related research and apply SA into different domains, several authors have proposed definitions of SA with the description of mechanisms developing a shared understanding of a situation. For instance, [Nofi \(2000\)](#) defined SA as a shared awareness of a particular situation, and [Perla et al. \(2000\)](#) claimed that shared SA implies that we all understand a given situation in the same way. [Rodney Wellens \(1993\)](#) described SA during collaborative activities through a model of distributed decision-making and defined SA as “the sharing of a common perspective between two or more individuals regarding current environmental events, their meaning and projected future.” [Endsley's \(1989\)](#) approach is different in that they defined SA as the degree to which every team member possesses the SA required for his or her responsibilities. With [Bass et al. \(1999\)](#) realizing the functional model of network situation

awareness based on multi-sensor and data fusion, the concept of SA is growingly introduced into cyberspace ([Lif et al. 2017](#)). In these fields, the SA is stated as a process of continuous extraction of systemic information along with integration of the information with previous knowledge to form coherent mental pictures and use of those pictures in directing future perception and anticipating future need. As the next generation of power supply system, smart grid is a complex environment with many interactions among human operators, data collectors, and human-machine interfaces. The composition and characteristics of smart grid make the development and maintenance of a sufficient SA a highly challenging task.

Historical Background

Although many attempts have been made to form a universally accepted definition of SA, it is still difficult to formulate a comprehensive definition that captures all aspects of SA. According to the situation awareness and safety survey proposed by [Stanton et al. in \(2001\)](#), three SA definitions including three-level model ([Endsley 1995](#)), the perceptual cycle model ([Smith and Hancock 1995](#)), and activity theory model ([Bedny and Meister 1999](#)) have been widely accepted and applied by the majority of circumstances within different domains.

Three-Level Model

[Endsley's](#) three-level model defined SA as the perception of the elements in an environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future.

- **Level 1 SA – Perception:** As the lowest level of SA, system operators need to gradually receive the information related to their goals. For instance, in the context of aviation, SA is associated with the pilot's perception of information from aircraft instrumentation, weather condition, the behavior of the aircraft, and

the terrain control. Besides collecting the data individually, Bass et al. (1999) proposed a function model of SA based on multi-sensor and data fusion which demonstrated that the next-generation network's intrusion detection system (IDS) needs to fuse massive data collected by heterogeneously distributed network sensors so as to realize the cyberspace SA.

- **Level 2 SA – Comprehension:** The data collected from the Level 1 SA can be integrated and synthesized to produce an understanding of the relevance to present tasks. The comprehension level is a process of achieving situation understanding through identifying the most critical information of the SA elements from Level 1 SA. Using the perceived information, system operators are capable of detecting any deviations between the actual system state and the expected state and further decide on the most necessary and appropriate actions to implement. In contrast, a lower Level 2 SA would fail to proceed to an effective implementation of necessary actions which may mitigate the system capability and reliability.
- **Level 3 SA – Projection:** As the final step and the highest level of SA, projection is a prediction of the future behavior and status of system components and elements in the environments (e.g., projected potential aircraft conflicts). For example, anticipation of the predicted future situation provides air traffic controllers with sufficient time to prevent and resolve aircraft conflicts and plan a course of actions to achieve their goals. Accuracy of the projection is highly dependent upon the level of Level 1 SA and Level 2 SA. System operators with a high Level 3 SA are able to develop a set of strategies and responses to undesirable situations in advance.

Perceptual Cycle Model

In contrast with the Endsley's three-level model (Endsley 1995), Smith and Hancock's perceptual cycle model (PCM) (Smith and Hancock 1995) does not distinguish between the SA processes

and product. This approach is a development of Neisser's model (Neisser 1976) of the perceptual cycle which emphasized the impacts that the knowledge of how world works leads to a better understanding and interpretation to current situation and highlights complex environmental information modifies human thoughts which in turn directs their actions. Moreover, the interaction between the individual and the world will make the perceptual cycle model more dynamic than others.

Activity Theory Model

Activity theory model is an interactive subsystem approach to situation awareness that presented by Bedny and Meister in (1999). As an information processing approach, the model comprises orientational, executive, and evaluative eight functional blocks with dedicated purpose, connected through forward and feedback loops. The involvement of processes is dependent on the nature of the task and the goals of the individual. Each functional block in activity theory model holds a specific task in the development of situation awareness and structure of activity. The content of each functional block may vary based on the nature of dynamic situation.

SA Challenges in Smart Grids

Endsley and Connors (2008) described "SA demons," such as data overload, workload, and increased complexity, which are capable to every domain. In paper Endsley and Connors (2008) and Connors et al. (2007), these authors discussed the demons and challenges for SA in distribution control center and power transmission. In practice, it's very important to identify the factors governing SA in smart grids since electrical disturbance could be initiated by operator errors.

- *Software applications:* There are various applications and tools such as alarm processing, state estimator, and contingency analysis that are used by smart grid operators

to monitor and control the power system. Failures in any of these applications or tools can result in absence of early warning of deterioration of the system state, which may result in delayed and absent response from the operators and contributed to the large-scale blackout. The blackout in the US-Canada region in August 2003 (US Force 2003) is a typical example of failures in software applications which cause a huge economic loss for those two countries.

- *Measurements:* Real-time measurement is the key part of real-time grid analysis and sufficient SA maintenance. Operators use the data collected from simple sensors and advanced equipment such as the wide-area measurement systems (WAMS) and the phasor measurement units (PMU) to be aware of critical events. Missing real-time information, due to a failure in the communication systems or any measurement devices, may affect operator's SA and result in lower level of certainty and a false sense of smart grid security.
- *Environmental factors:* During emergencies, system operators often have to deal with a large amount of data and alarm overload. The critical information of the system may be neglected, and the attention of the operators may be attracted by a small part of data that is less important or even unrelated to the main objective if the data and the alarms are not effectively integrated and presented using advanced decision support systems. In addition, graphical user interface (GUI) is used to detect abnormal situations. However, the complexity in GUI may make the perception and interpretation of information collected a highly challenging task. Hence, besides using GUI, operators often have to scan several computer monitors and many pages of supervisory control and data acquisition (SCADA) data to reach a single decision.
- *Automation:* Increasing the level of automation can significantly reduce the operators' workload in smart grids. However, highly automated systems may leave operators detached from the control systems and even possibly become unaware of the actual system status. This is usually called "out-of-

loop" syndrome that was defined by Endsley (2018). In practice, operators may have a decreased ability to understand the system and to detect automation failures. As a result, the operator's SA is significantly compromised where human intervention is needed.

- *Individual factors:* Operators' experience, training, and professionalism are also the factors that may contribute to poor performance and insufficient SA in smart grids. For example, the union for the coordination of transmission of electricity (UCTE) incident (UCTE 2007) in 2006 is a representative example of the impact of individual factors. A lack of experience with insufficient training on the latest technologies or inappropriate actions may lead to cascading line outages and the large-scale blackout.
- *Data and information communication:* The Italian blackout (UCTE Investigation Committee et al. 2003) of 2003 illustrates the importance of effective data and information communication and coordination between system operators, especially in highly interconnected networks. Insufficient communication may lead to ineffective coordinated actions, which result in inadequate SA between system operators.

Key Applications

Situation awareness is involved in applications related to the development and maintenance of the smart grid reliability such as state estimation (Stae), anomaly detection (AnoD), and security analysis (SecA), which are deeply relied on the collected information from phasor measurement units (PMU) and wide-area measurement systems (WAMS) that are implemented in the smart grid.

- *SA integrated with StaE.* Research in CHEN et al. (2016) integrated the linear state estimator into situational awareness applications based on real-time synchrophasor data. Compared with the conventional state estimator,

the proposed system guarantees solutions and performs in real time at the PMU data rate. With guaranteed and accurate state estimation solution and advanced real-time data analytic and monitoring functionalities, the system is capable of assisting operators to assess and diagnose current system conditions for proactive and necessary corrective actions.

- *SA assisted with AnOD*. Motivated by growing concern about failures and attacks to distribution automation equipment, researchers employed micro-PMUs to proceed the anomaly detection (Jamei et al. 2017) and situation awareness in a distributed smart grid. By collecting the phasor data stream of a single micro-PMU without knowledge of the grid interconnection parameters and correlating the phasor streams across multiple micro-PMUs using electrical properties of the grid, two methods are employed to design the anomaly detection rules.
- *SA combined with SecA*. A lot of threats occur in a very short time but have huge impacts on smart grid and disturb its normal operation. To address this issue, Wu et al. (2016) proposed a security situational awareness mechanism for smart grid based on big data analysis. To get high accuracy for the big data analysis, fuzzy cluster-based association method is used to realize the preliminary analysis about the collected security facts from multiple devices over the long term. Then, game theory and reinforcement learning are introduced for security situational analysis.

Conclusion

This entry provides a fundamental of SA in smart grids including definitions, challenges in smart grid due to insufficient SA, and SA key applications in smart grids. Within these contexts, this entry provides a guideline for designing smart grid system in a way to achieve sufficient SA.

WBAN; Wireless Body Area Networks

Definition

A WBAN is a network that body sensors utilize to communicate with each other, by sending and storing data across sensors.

Background

Wireless body area networks (WBANs) are a highly popular communication system in the current market. As such it will transfer data with the help of a personal server and a Wi-Fi connection to a hospital so that doctors and caretakers can survey the results and statuses of the sensors on a patient's body. WBAN allows doctors to use special treatment sensors, such as EEGs and EKGs outside of the hospital, permitting users to leave the hospital and go about their daily lives without being required to stay in a hospital due to the equipment. WBANs also allow a network that hospitals can incorporate more easily into their patient survey programs so that doctors and nurses can react more easily to unusual readings of monitoring devices. Ever since initial proposals have been made for WBANs, the network has been getting stronger and more efficient. Currently WBANs operate on the 2.4 GHz frequency which is becoming increasingly overpopulated with modern technologies such as phones using Bluetooth and Wi-Fi, for example. One very promising solution to the problem of exhaustion of resources is the switch from a 2.4 GHz waveband to a higher range such as 5–10 GHz and, as will be discussed in this section, the 60 GHz waveband. Since WBANs are becoming so increasingly popular and since resources in the 2.4 GHz range are as limited as they are, switching to a larger waveband that can sustain more WBAN sensors seems like the optimal solution. As will be discussed in the next section, 60 GHz promises a lot of benefits and improvements over the 2.4 GHz waveband, but also brings with it some imperfections that have to be elaborated on and explored. There are still some issues that need attention, such as battery life, antenna design, maximum distance of transmission and performance, security issues, and

60 GHz in WBAN and mm-Wave Technologies, Fig. 1
The overarching challenges of 60 GHz WBAN research

environmental interference. These are the challenges researchers tackle when trying to optimize WBANs at 60 GHz with the major ones being shown in Fig. 1.

Potential Solutions for 60 GHz WBANs

Comparing 60 GHz to 2.4 GHz Waveband

The current standard waveband for almost all wireless applications and accessories is the 2.4 GHz waveband. It is used for all kinds of things, ranging from phones to laptops to Bluetooth and Wi-Fi signals, and has been this way since the 1950s. As our technology keeps improving alongside networks and wireless devices, the 2.4 GHz waveband becomes more and more cluttered with possibly interfering signals and may run out of usable frequencies in coming years, causing trouble across networks through incomplete signals and interruptions.

There have been some studies researching and comparing 2.4–60 GHz to see whether or not it would be beneficial to swap frequencies. One very crucial aspect of comparison is the carrier-to-interference ratio (CIR) of both wavebands. CIR compares the amount of successfully transmitted data through a network to the loss of information across a network to result in a ratio that can be used to model efficiency in transmission of data across nodes in the case of WBAN. CIR is most notable if other signals on the same wavelength are present. Especially in

hospitals, this then plays a large role considering the amount of medical equipment and the amount of WBAN sensors in a possibly densely populated area. A study considering movement of nodes within a system by moving body parts and nodes of a WBAN system attached to them shows that 60 GHz promises a stronger CIR compared to 2.4 GHz under the circumstances given (Wu et al. 2015).

Going away from intra-network interference and taking into account inter-network interference (Fig. 2) show that CIR of 2.4 GHz is heavily affected by even one other BAN or WBAN network in the same area. 60 GHz becomes a lot weaker across larger distances which is why it can be beneficial to apply this type of wavelength rather than the 2.4 GHz frequency as WBAN systems increase. This ultimately allows densely populated areas such as hospitals to deploy multiple WBAN systems at once while losing the least amount of data as possible (Cotton et al. 2010).

Environmental Interferences

While the 60 GHz frequency doesn't struggle all too much with inter-network interference, it is a little undermined in its range. Only because it doesn't struggle much with other networks doesn't mean that it doesn't struggle with keeping its communication across nodes to a maximum. Environmental effects and humans affect the strength of the 60 GHz signal by blocking its line of sight or otherwise disturbing the frequency. A 60 GHz WBAN node with any of its antennas has rather poor penetration power and may lose some information across large distances or through obstacles and interfering objects in its way. This is nothing new; 2.4 GHz and other frequencies experience the same type of interference. It has large precision across short distances, but that fact diminishes if nodes are further apart since 60 GHz has large oxygen absorption loss and a poor value of penetration across objects. This is a problem that 60 GHz doesn't necessarily fix, but can hold up, compare to, and possibly improve upon previous methods such as the 2.4 GHz and ultra-wideband frequencies (Liu et al. 2015).

60 GHz in WBAN and mm-Wave Technologies, Fig. 2

Diagram demonstrating inter-WBAN interference

60 GHz in WBAN and mm-Wave Technologies, Fig. 3

Interfering signals are weakened by intercepting objects

A similar study found similar results by placing interfering signals (a blocking human system) between two systems of 60 GHz WBAN networks. Using the Friis formula, the results show that 60 GHz wavebands are interfered less if there is a blocking shadow signal to reduce the interference. The model the authors use for their research incorporates free space loss and the three users (interfered/interfering/blocking) to reach their conclusion: in the case of NLOS (non-line of sight), the interference strength of 60 GHz inter-WBAN is below power sensitivity (Akimoto et al. 2017). This means that even though 60 GHz waveband signals easily lose

strength and connectivity across larger distances, it can turn out to be a benefit rather than a drawback. The system encapsulates itself, only being able to communicate with nearby nodes and can't be interfered as easily by outside sources, especially if that outside source is intercepted by a blocking object such as a shadow in Fig. 3.

Researchers also have evaluated intra-WBAN interference alongside inter-WBAN interference to see if there may be any problems in short distance communication across WBANs. This was done by using a flashlight as a directional millimeter-wave WBAN to prove their study. It has been concluded that a millimeter-wave

WBAN does not consider body attenuation when using directional antennas, at least as described in specific example cases of intra-WBAN interference. This finding is very useful for future research as it shows that body attenuation is not a problem for line of sight (LOS) WBAN networks at 60 GHz. The intra-WBAN interference is almost negligible in this type of network and makes 60 GHz wavebands stand out from others (Akimoto et al. 2018).

In review, CIR is reduced since it is more easily intercepted than 2.4 GHz wavebands, there are less networks currently out in the market using 60 GHz as a waveband, and connection between nodes is stronger than other frequencies; 60 GHz seems to be the strongest contender that can currently be implemented in the medical field and as a communication tool.

Antennas Used in WBANs

As mentioned in the previous section, 60 GHz operates the strongest if used at low distances and has diminishing returns at larger distances. There are studies going on to develop methods and structures for antennas in a WBAN to stabilize connections and to maximize gain. There are many factors to consider when designing an antenna, such as detuning, changes in input impedance, changes in transmission power and accuracy, changes of radiation patterns, battery life, robustness and stability on the body, weight, and overall performance of the antenna over time. A crucial factor that will also need to be considered is the interfering obstacle that is the body of the user. Path loss on a human body ranges from 57 to 88 dB and can cause large amounts of lost packages in WBAN communication and has to be considered (Pellegrini et al. 2013).

Antennas that were considered by this source all have their benefits and drawbacks (Pellegrini et al. 2013). The Yagi-Uda antenna establishes a good connection, but doesn't optimize gain. An antenna using a microstrip-fed patch array is close to insensitive to phantoms and objects. Textile antennas have the benefit of being woven or otherwise inserted into clothes and that the human body has barely any effect on the antenna and the transmission of its signals.

Woodpile EBG-based antennas have a higher maximum directivity of +5 dB if the standard is comprised of monopole antennas. The final antenna described is the reconfigurable antenna that switches the beam direction of the radiation pattern which leads to better security, overcomes shadowing, minimizes unwanted illumination of body area, but otherwise doesn't see much use in WBAN systems (Pellegrini et al. 2013). Considering which antenna to use may depend on the desired structure of the WBAN on humans, be it that the nodes are attached to feet and arms or head and chest. Some benefit more than others in different situations.

While that article reviews the antennas that existed around 5 years ago, there are also advancements in design of antennas. Previous antennas in WBAN (prior to 2015) were already in a dual-band or broadband format but required additional components and structures to work (Zhu et al. 2016). In WBAN, minimizing effect on human bodies, minimizing the size of an antenna, and maximizing throughput are at the core of design of antennas. The proposed antenna attempts to improve upon its predecessors in order to improve performance. This has been happening for a long time (prior to 2010) and is an ongoing field of research. Designing an antenna is not limited to the factors mentioned above, however. While the efficiency of signals and attenuation along with size are large factors of design, optimization doesn't stop there.

Algorithms to Extend Battery Life

WBANs and their antennas, just like any other electrical device, require a power source. With WBANs, it can become tricky to implement batteries and energy-efficient methods of dealing with energy output as there are multiple ways to attach them to humans. Some WBANs may simply be attached to clothing, but some are implanted within the tissue and skin of a human. Once a battery runs out of power, it is extremely difficult to replace once within a patient's skin. Researchers have been looking for methods to reduce energy consumption and optimize battery usage to make this issue less apparent.

A proposed solution is to put the nodes in a WBAN to sleep if they are not in use. This method needs to take into consideration the types of transmission within a node. Messages can be delivered in parts and rather slowly or all at once. There are also different ways of assigning priority and emergency messages/packages to be sent. There have already been studies to observe and analyze these different types of packages and their consumption and that propose the above-mentioned solution through their findings (Jacob and Jacob 2017).

Combining power-saving strategies is also becoming more important. A very recent proposal (2018) is to use an optimal energy consumption algorithm based on an artificial bee colony structure (Yan et al. 2018). Nodes using this algorithm will be considering the remaining energy of a node, priority of nodes and messages, path costs of transmitting packages, and difference in path energy ratios when transmitting data. This combines previous studies under an algorithm that is based off a bee colony structure (Fig. 4). Packages find the most efficient and fastest path to travel across multiple or few nodes (depending on algorithm results) in order to maximize battery efficiency while keeping traffic of packages consistent. This algorithm is claimed to be better suited for WBAN systems than ant colony and genetic algorithms. While

this algorithm maximizes battery efficiency, there are other methods and algorithms that specify in different aspects of WBAN systems, algorithms that improve nodes in different ways.

Algorithms to Enhance Performance

The previously mentioned artificial bee colony algorithm already considers communication across nodes, but mainly focuses on that one algorithm for transferring packages. There are however many multiple ways of getting packages from point A to point B especially if there are intermediary nodes that can be used to describe a different path. These ways include, but are not limited to, two-way relay cooperation links, one-way relay cooperation links, and direct transmission between WBAN sensors. Most systems specialize in one of these links and always use the same type of transmission for every type of package.

Studies to analyze and compare the performance of these transmissions have been made and come to a conclusion that single-hop links (Fig. 5), which work in a linear fashion to send information across nodes in a 1-to-1 relationship with a transmitter including a message buffer and a receiver are more energy efficient than dual-hop links (Fig. 6), which uses intermediary nodes as transmitters in the case of NLOS situations

60 GHz in WBAN and mm-Wave Technologies, Fig. 4 An example of an artificial bee colony node setup

60 GHz in WBAN and mm-Wave Technologies, Fig. 5
Single-hop link

60 GHz in WBAN and mm-Wave Technologies, Fig. 6 Dual-hop link

between two nodes. A solution proposed on the basis of this finding would use methods to also harvest energy from the environment while utilizing a single-hop transmission system (Mosavat-Jahromi et al. 2017).

A proposed communication system uses a hybrid switching scheme to quickly switch between these aforementioned methods of communication to maximize efficiency and speed while attempting to keep battery usage low (Waheed et al. 2018). This improves performance significantly for both LOS and NLOS since different links optimize one of either signal and since they can be switched to within short amount of times. This switching also results in a better packet-error-rate across nodes. Another benefit of this is that WBAN systems could be implemented with less implants and wearables due to a more effective communication framework.

Some ways of communication benefit under certain circumstances, and being able to switch between them and having an algorithm coordinate that switching is certainly a step in the right direction.

Simulation Platforms

While research is expanding in multiple directions, there is not a lot of hardware currently on the market to support testing at 60 GHz wave bands. There are some open-source and build-your-own type models that can be built to work with the frequency, but there are also some alternatives that may not be entirely accurate but useful to research as they can still arrive at general conclusions.

In general, the usage of a universal software radio peripheral (USRP) is recommended since it is standardized hardware for wireless communication. While models of USRP are not able to communicate at 60 GHz frequencies, they do have the ability to communicate beyond the 2.4 GHz threshold. The ability to do so allows USRPs to access different wavebands and therefore simulate and give similar results as if the simulation were done with a 60 GHz device. It is an alternative to test new research and methods, and while it isn't completely accurate, it is a step in the right direction, and results can be derived

for 60 GHz frequencies by looking at the results given by USRP.

One of the first accessible, build-your-own models for 60 GHz communication is a software-designed radio (SDR)-based, open-source front-end testbed published in early 2015. There were earlier machines that proposed to do the same, but this one is made with researchers and budgets in mind, making it easy to obtain all required parts and using the provided software. Like many other SDR-based machines, this device is used alongside a USRP. The combination of ease of construction and provided software made this model very valuable when it was released, but at this point in time, it is no longer the only one (Zetterberg and Fardi 2015).

A platform that was released at the end of 2016 called OpenMili (Zhang et al. 2016) expands on the functions of the previously mentioned testbed by allowing more customizability for users. This is a continued iteration of previous models and breaks through some very important limitations. The publication once again mentions in detail how all hardware components, which are easily obtainable, work together to provide a strong tool for 60 GHz experimentation. The key point that makes this model stick out is its customizability in a lot of different areas. The phased-array antenna included in the testbed, for example, is programmable and compatible with different interfaces and antennas. OpenMili is also optimized toward giga-samples per second (Gsps) sampling and Gsps processing rates to simulate a faster communication environment for 60 GHz communication. OpenMili declines the usage of USRP for communication as it seems to lower the sampling rate which is something OpenMili aims to optimize. It strays away from conventional models to create its own optimized communication network based off hybrid schemes, but not on USRP directly. As such it is able to perform at better speeds than previous testbeds at the time (Zhang et al. 2016).

Since then there has been a more recent, more promising device that tackles the lack of hardware to support 60 GHz communication. The testbed is called X60 and behaves similarly to the OpenMili platform. The SDR-based, multi-

gigabit WLAN, X60 60 GHz testbed has high customizability as well with adjustable MAC, PHY, and network layers alongside an antenna array that can be modified similar to OpenMili. The fact that X60 allows users to fully control MAC and PHY layers grants them the chance to test their algorithms and techniques on multiple layers while being able to also survey each layer fully. These additional features grant testers a greater potential in testing 60 GHz communication and performance of the X60 under different circumstances, including LOS and NLOS environments (Saha et al. 2017).

While the abovementioned devices are really promising for research in 60 GHz, their production cost is still rather high. There are not many 60 GHz testbeds out on the market as of right now, but the USRP-only alternative seems viable for low-scale testing and familiarizing with the concept of wireless communication beyond the current 2.4 GHz norm. Other testbeds are still on the rise, and some may soon even overshadow those mentioned here, but for now, there are not a lot of ways to test research done on 60 GHz other than with some testbeds.

Further Direction and Discussion

In all of these research challenges, a basic understanding of wireless communication is recommended to start delving into more detail about the chosen challenge. Areas such as environmental interference, inter-WBAN interference, and intra-WBAN interference will require to be able to correctly apply communication methods such as single- and dual-hop links or otherwise research new networking methods to improve current CIR and other issues that still arise during communication. Battery life and performance enhancing algorithms also go hand in hand. Optimizing one requires an understanding of the effects of the other and how to handle both. The challenge becomes interdisciplinary; between software and circuit design for antennas and handling communication strength and accuracy, WBANs at 60 GHz require strong design decisions and a result of application of all skills mentioned above.

Research in this field is looking for improvements in each field mentioned above, even hardware development. If funding is scarce, researchers should look to an alternative hardware to test new ideas on, such as USRP communication devices. With more funding and more knowledge, research can then expand into machines that accurately simulate 60 GHz wavelengths. Regardless of the challenge or field of 60 GHz research, there are a lot of resources to aid in understanding and learning to overcome these issues. Researching a field of challenge can aid in understanding the ins and outs, but hands-on experience will be very important in fully bridging the gap between theory and execution.

Conclusion

The 60 GHz waveband promises a bright future for WBAN networks. With reduced CIR, improved communication across short distances, difficult interception by other networks, and possibly better speeds and implementation among other points, 60 GHz improves what 2.4 GHz, UWB, and other frequencies had to offer. Ongoing studies in both 60 GHz and other frequencies may be applied to the same category of WBAN, with algorithms to solve remaining issues such as battery life and optimal antenna design. Switching systems from 2.4 to 60 GHz may take a while, but starting with WBAN, which is easy to switch over, it may happen eventually. It will have to; since we are running out of space in the 2.4 GHz waveband and since 60 GHz seems so promising, there doesn't seem to be a point not to. There have been vast improvements for optimizing path loss and communication speed and accuracy while also keeping battery life in mind, but those aren't perfect yet. Studies are still somewhat spread out, and, since there is no standard for 60 GHz WBAN systems yet, it is hard to combine all studies into one general design while implementing all improvements. Once these different fields of research reach a common optimized product, improvements can keep happening, but right now all information is spread out across disciplines and split between

2.4 GHz advancement and 60 GHz advancement. Both may or may not be applicable in either situation, but a standard should still be created to apply new solutions to.

Sleep Monitoring Using WiFi Signal

Xuyu Wang, Chao Yang, and Shiwen Mao
Department of Electrical and Computer
Engineering, Auburn University, Auburn, AL,
USA

Synonyms

Remote health sensing using WiFi signal; Vital sign monitoring using WiFi signal

Definition

Sleep monitoring is to detect and analyze the activities of a subject during sleep, such as res-

piration rate, heart rate, and posture, to provide important information on the subject's health conditions (Pantelopoulos and Bourbakis 2010; Chen et al. 2013; Wang et al. 2018a,b). In addition, sleep quality can also be inferred by analyzing such vital signs. For example, monitoring the breathing signal while the patient is sleeping can help to detect sleep disorders, as well as sudden infant death syndrome (SIDS) (Hunt and Hauck 2006) and apnea (Nandakumar et al. 2015). However, most traditional sensors are intrusive, such as a capnometer (Mogue and Rantala 1988) or a pulse oximeter (Shariati and Zahedi 2005). A patient can hardly sleep comfortably with these sensors attached to the body. Because of the restrictions of traditional sensors, effective and comfortable sensors are in a great demand for long-term and contact-free vital sign monitoring.

Historical Background

Recently, sleep monitoring are implemented using different techniques, including RF radar, RFID, motion sensors, and acoustic-based sensors. Vital-Radio is an RF radar-based technique, which uses a frequency-modulated continuous wave (FMCW) radar to monitor breathing and heart rates (Adib et al. 2015). It requires a customized hardware using a large bandwidth from 5.46 to 7.25 GHz. Moreover, other radar-based vital sign monitoring techniques are proposed, including ultra-wideband radar (Salmi and Molisch 2011) and Doppler radar (Droitcour et al. 2009; Nguyen et al. 2016), which all require customized hardware with a relatively high cost and operates with a large spectrum band. RFID tags are used for vital sign monitoring too. For example, TagBreathe estimates breathing rates with phase information by grouping the signals with the same channel index (Hou et al. 2017). In fact, the system does not work very well in the US, where the RFID frequency range is from 902.5 to 927.5 MHz with 50 channels; the channel hopping among the 50 different frequencies leads to a large latency. To address this issue, the AutoTag system incorporates a recurrent variational autoencoder

for unsupervised apnea detection with RFID tags, as well as a frequency hopping offset mitigating technique to enable FCC-compliant RFID systems for realtime applications (Yang et al. 2018). Zephyr is a motion sensor-based monitoring technique, which can monitor breathing rates by fusing the data from the accelerometer and gyroscope available in many smartphones (Aly and Youssef 2016). In addition, HeartSense can even achieve a 1.03 bpm median absolute error for heart rate estimation using different gyroscope axes with a probabilistic model (Mohamed and Youssef 2017). The sleep monitoring system uses the built-in accelerometer to estimate breathing rate and body position with a smartwatch (Sun et al. 2017). For acoustic signal-based sensors monitoring, the apnea detection system employs an active FMCW sonar built in a smartphone to monitor the breathing signal (Nandakumar et al. 2015), while SonarBeat considers sonar phase information for breathing rate estimation with a continuous-wave (CW) radar (Wang et al. 2017a).

Although different techniques have been proposed for sleep monitoring, contact-free and long-term vital signs monitoring at low cost are still of high interest. Currently, WiFi-based systems have become an effective solution for sleep monitoring, as shown in Fig. 1, because of the wide availability and the low hardware

requirements of WiFi. Received signal strength (RSS) in WiFi networks has been used for vital sign monitoring in Abdelnasser et al. (2015). Moreover, by slightly modifying the device driver, channel state information (CSI) can be extracted from off-the-shelf WiFi network interface cards (NIC) (Halperin et al. 2010), which reflects represents fine-grained channel information. CSI amplitude (Liu et al. 2015) and phase difference (Wang et al. 2017b,c) have been leveraged for sleep monitoring. WiFi-based techniques for sleep monitoring will be reviewed in detail in the remainder of this article.

Preliminaries of WiFi Signals

WiFi standards, such as IEEE 802.11a/g/a/ac, all use the orthogonal frequency-division multiplexing (OFDM) technique in the physical layer (PHY), which can effectively overcome frequency selective fading in indoor environments. With OFDM, the total spectrum is divided into multiple orthogonal subcarriers, while data is encoded and mapped to these subcarriers to be transmitted using the same modulation and coding scheme (MCS) (Wang et al. 2016a, 2017d). At the receiver, the wireless signal is down-converted to the baseband. Using the serial-to-parallel (S/P) transform and fast Fourier transform (FFT), the subcarriers can be converted from the time domain to the frequency domain as in Fig. 2. For some commodity NICs, such as the Atheros AR9390 chipset (Xie et al. 2015) and Intel 5300 NIC (Halperin et al. 2010), there are open-source device drivers that allow reading the CSI for received packets, which represents fine-grained PHY channel measurements, containing rich information on channel features such as shadowing, power distortion, and multipath effect.

Let H_i be the CSI value of subcarrier i , which is a complex value, as

$$H_i = |H_i| \exp(j \angle H_i). \quad (1)$$

where $|H_i|$ and $\angle H_i$ are the amplitude response and phase response of subcarrier i , respectively.

Sleep Monitoring Using WiFi Signal, Fig. 1 Sleep monitoring using WiFi signals

Sleep Monitoring Using WiFi Signal, Fig. 2 CSI and RSSI in OFDM based WiFi systems

The measured phase of subcarrier i , $\angle \hat{H}_i$, is Wang et al. (2017b,c)

$$\angle \hat{H}_i = \angle H_i + (\lambda_p + \lambda_s)m_i + \lambda_c + \beta + Z, \quad (2)$$

where m_i is the subcarrier index of subcarrier i , β is the initial phase offset at the phase-locked loop (PLL), Z is the measurement environment noise, and λ_p , λ_s , and λ_c are the phase errors from the packet boundary detection (PBD), the sampling frequency offset (SFO), and the central frequency offset (CFO), respectively.

The measured CSI phase data is not stable because of the randomness in the RF chain, but the measured *phase difference* (i.e., the difference of phases from two adjacent antennas) can be exploited for vital sign monitoring, which is given by

$$\Delta \angle \hat{H}_i = \Delta \angle H_i + \Delta \beta + \Delta Z, \quad (3)$$

where $\Delta \angle H_i$ is the true phase difference of subcarrier i , $\Delta \beta$ is the unknown difference in phase offsets, which is a constant, and ΔZ is the noise difference. Obviously, $\Delta \angle \hat{H}_i$ is a stable signal, because the randomness from PBD, SFO, and CFO are all canceled.

On the other hand, RSSI can be described as a function of sender-receiver distance d with a path loss model, as in Wang et al. (2014)

$$\text{RSSI} = P_0 - 10n \log_{10}(d) + w, \quad (4)$$

where P_0 is the RSS value at a reference distance d_0 ; n is the path loss exponent (which is different from 2 in free space to 4 (or a higher value) in indoor environments), and w is a zero mean Gaussian noise. Measurements show that RSSI not only fluctuates over distance but also varies over time. Thus, a small change of the propagation environment will cause large changes in RSSI, which can also be exploited for vital sign monitoring.

Key Applications

RSS-Based Vital Sign Monitoring

UbiBreathe is a WiFi RSS-based technique, which can capture the human respiration signal with RSS values obtained from off-the-shelf WiFi devices (Abdelnasser et al. 2015). In particular, the system uses a cellphone as receiver and a laptop as transmitter. To extract the respiration signal, raw RSS values are firstly filtered by a band-pass filter with cutoff frequency from 0.1 to 0.5 Hz. Then, noise is further removed by a discrete wavelet transform (DWT) and outlier removal. Breathing rate can be then estimated using FFT. The system also detects abnormal breathing symptoms such as apnea using a threshold method, while the subject is sleeping. Experimental results show that the estimation error of breathing rate of UbiBreathe is less than 1 beats per minute (bpm). However, the system has special location requirements for the user and two devices. The system can only detect human breathing signal when the receiver is on the user's chest or the user is in the LOS path of the transmitter and receiver.

However, RSS values collected from 2.4 to 5 GHz WiFi devices can hardly capture the human heart rate because of the low resolution of RSS values. In addition, the received RSS values can be easily corrupted by other persons nearby, because of the omnidirectional propagation of WiFi signals. To address this issue, the mmVital system employs 60 GHz WiFi devices to measure both breathing rate and heart rate (Yang

et al. 2016). Since the 60 GHz WiFi signal is transmitted in a highly directional beam, the subject can be easily separated from other unrelated objects/people in the environment. In fact, it is necessary for the system to first identify the location of the user, before monitoring vital signs. To deal with this challenge, the authors develop a novel human finding technique to differentiate the reflections from the user and other surrounding objects. With this technique, the system can locate two users and monitor their vital signs simultaneously. The evaluation of the system shows that the accuracy of human finding subsystem is up to 98.4% and the mean errors of breathing rate and heart rate estimations are 0.43 and 2.15 bpm, respectively. The accuracy of the system is high, but there are still some deficiencies for the system. For example, the user should stay in the LOS or the reflection path of the transmitter and receiver, and the special 60 GHz hardware is required for this technique.

CSI-Based Vital Sign Monitoring

CSI can provide much more information on the wireless channel than RSS. Several CSI-based systems have been proposed for more accurate vital sign monitoring. The amplitude of CSI is firstly used to detect breathing rate. The WiFi-sleep system monitors human respiration and different sleeping postures by analyzing the amplitude of CSI (Liu et al. 2014). To denoise the CSI amplitude and remove outliers, the raw received signals from all subcarriers are firstly filtered by DWT. Because the sensitivities of CSI values over subcarriers are different, some of the signals may not be useful. The system only chooses the most sensitive signal to estimate the human breathing rate. Furthermore, the system also analyzes the effect of human sleeping postures on breathing estimation. To reduce the impact of different sleeping postures, the system will automatically choose the best antenna pair to obtain the most appropriate CSI signal.

In addition to breath monitoring, another work can also estimate heart rate from CSI amplitude (Liu et al. 2015). Different from the breath-

ing signal, which can be obviously observed in CSI, the heart signal is very weak and cannot be easily detected from raw CSI measurements. To focus on heart rate monitoring, the received signal is filtered by a band-pass filter with the cut-off frequency from 1 to 1.33 Hz. The experiment results with this technique show that the mean estimation errors of heart rate and breathing rate is 2 and 0.3 bpm, respectively.

Compared with CSI amplitude, CSI phase is more robust for monitoring vital signs at different distances and orientations. However, due to the asynchronous options of the transmitter and receiver, the measured phase information cannot be directly used. To this end, the PhaseBeat system leverages the phase difference between two receiving antennas to monitor vital signs (Wang et al. 2017b). With phase difference data, the robustness of respiration rate estimation is greatly increased. In addition, PhaseBeat can detect the breathing signal at longer distances, e.g., when the transmitter is 11 m away from the receiver, the median error of breathing rate estimation is 0.25 bpm. PhaseBeat can also detect heart rate with a 1 bpm median error.

Although distance has less impact on phase difference, the sensitivities of CSI phase difference and amplitude can be affected by the reflection from surroundings or the posture of the user (Wang et al. 2016b). Figure 3 shows a colormap for breathing signals using CSI phase difference and amplitude, which illustrates the independence of the sensitivities of CSI phase difference and amplitude. To enhance the robustness of CSI-based systems, the bimodal data system ResBeat leverages not only phase difference but also amplitude (Wang et al. 2017e). ResBeat implements an adaptive signal selection algorithm to ensure that only the most sensitive amplitude and phase difference be used for extracting respiration signal. The final estimation result is calculated with the combination of both amplitude and phase difference data. The system is shown to remain robust, even though the location or the posture of the user is changed. The success rate of human respiration rate estimation is higher than 90% in the experiments.

TensorBeat (Wang et al. 2017c)	✓	×	✓	×	×
TR-BREATH (Chen et al. 2018)	✓	×	✓	×	×

The TensorBeat system is proposed to handle the case of multiple persons with tensor decomposition (Wang et al. 2017c). First, TensorBeat uses CSI phase difference data between pairs of antennas to create CSI tensors, and then applies canonical polyadic (CP) decomposition to decompose the tensor. In addition, a stable signal matching algorithm is utilized for obtaining the decomposed signal pairs for each person. Finally, a peak detection method is exploited to estimate the breathing rates for multiple persons. Experimental results show that TensorBeat can achieve high accuracy under different environments for multi-person breathing rate monitoring. In addition, TR-BREATH is also proposed for monitoring breathing rates for multiple persons (Chen et al.

2018). CSI values is used for obtaining time reversal resonating strength (TRRS) features, which can be thus analyzed by root-MUSIC and affinity propagation algorithms to estimate multiple persons breathing rates.

Table 1 provides a comparison of different systems for vital sign monitoring in detail.

Conclusions

We addressed the problem of sleep monitoring using WiFi signals in this article. The preliminaries of WiFi signals is first introduced. Then, an overview of existing techniques of vital sign monitoring using WiFi signals is provided, where RSS- and CSI-based techniques are discussed.

Acknowledgments This work was supported in part by NSF under Grant CNS-1702957.

Definitions

Unlike the infrastructure-based cellular network, D2D users (user equipment or mobile terminals) do not communicate via the central coordinator (base station, NodeB, or evolved NodeB) but operate as an underlay and communicate directly with each other or more hops.

Historical Background

A new generation of wireless communications, the fifth generation (5G), is predicted for beyond 2020. For 5G, much higher data rate and better user experience are two most obvious requirements (Saxena et al. 2020). To satisfy the first requirement, device-to-device (D2D) communication has been proposed, which allows two users in proximity communicate directly rather than go through the base station (BS). Correspondingly, three promising gains, i.e., proximity gain, reuse gain, and hop gain, can be offered to improve system performance (Han et al. 2019). Meanwhile, the gains can be achieved without having to invest in network-side hardware upgrades or new cell deployments.

Actually, the trait of D2D communication is not new in the cellular system. In academia, D2D communication was first proposed in (Lin and Hsu 2000) to enable multihop relays in cellular networks. Later the works investigated the potential of D2D communications for improving spectral efficiency of cellular networks, multicasting, peer-to-peer communication, video dissemination, machine-to-machine (M2M) communication, cellular offloading, content catching, and so on (Chatzopoulos et al. 2019). D2D also has been identified in some specifications such as Private Radio Communication System (PRCS), Japanese Handy Phone System (HPS), Digital Enhanced Cordless Telecommunications (DECT), etc. Many companies devote actively much in this research. Qualcomm, for example, is heading and has been very active recently. A prototype of “FlashLinQ” modem has been developed since 2006 to enable direct D2D communication

over a licensed spectrum. The prototype effort covers the protocol stack from the host software interface to the physical layer algorithm. “FlashLinQ” is even a new trademark registered in 2008 by Qualcomm (QUALCOMM 2008).

The key motivation for utilizing D2D communication underlying a cellular network is to keep local communication local. D2D communication shares the same resources with the cellular system while under the control of the evolved NodeB (eNB). In such a case, an eNB can still control the resource and power assigned for D2D transmission to limit the interference to the primary cellular networks. Although the concept of D2D communication as an underlay to a cellular network is not new in a cellular system, it is new in Long-Term Evolution (LTE) systems. As a result, some new challenges are incurred. The first key issue to be resolved is how to facilitate D2D communication in the licensed frequency band. Different from a centralized system where an eNB fully controls the data transmission which should be sent on the pre-allocated resources and user equipment (UE) terminals must synchronize with the eNB, devices would compete with each other for the resource in a distributed way in the D2D subsystem. Secondly, interference management in a hybrid network is a critical issue in that

the interference from D2D links can be expected to reduce the cellular capacity and efficiency and vice versa (Xu et al. 2012).

Foundations

- **System Model:** Indeed, such D2D communication is likely to become integral to the future beyond 3G world to form a hybrid network. Fig. 1 illustrates the basic and extended concept of D2D communication and hybrid networks. In Fig. 1, a UE device can communicate with another UE device directly or by the aid of a base station. Moreover, multiple D2D subsystems can share resources in a cell.
- **Used Spectrums:** Generally speaking, the spectrum that D2D communication may use can be categorized into inband and outband.
 - **Inband D2D:** The spectrums are used for both D2D system and cellular network. For the case that these two systems share same spectrum, it is called underlay inband D2D, and thus interference is incurred. In order to avoid the aforementioned interference issue, some researchers propose to dedicate part of the cellular resources only to D2D communications (i.e., overlay

Smart Device-to-Device Communication: Communication Establishment and Maintenance, Fig. 1 Illustration of D2D communication as an underlay to a cellular system

inband D2D). However, dedicated cellular resources may be wasted.

- Outband D2D: To eliminate the interference issue between D2D and cellular link, the D2D links exploit unlicensed spectrum. However, using unlicensed spectrum requires an extra interface and usually adopts other wireless technologies such as Wi-Fi Direct, ZigBee, or Bluetooth. In outband communications, the coordination between radio interfaces is controlled by either the BS (i.e., controlled) or the users themselves (i.e., autonomous). Outband D2D communication faces a few challenges in coordinating the communication over two different bands because usually D2D communication happens on a second radio interface.

Nevertheless, for the case of outband D2D, the interference in unlicensed spectrum is difficult to control. Especially, only cellular devices with two radio interfaces (e.g., LTE and Wi-Fi) can use outband D2D communications. More important, packets (at least the headers) need to be decoded and encoded because the protocols employed by different radio interfaces are not the same. Based on the above reasons, inband D2D has obtained wider research.

- Communication Establishment: Proximate device discovery, or proximate peer discovery, as defined by Qualcomm means the ability for a device to passively and continuously search for relevant value in one's physical proximity. Actually, it can be further identified in terms of radio interface and networking applications.
 - Discovery of radio interface feature: A device is able to discover and be discovered by other devices in radio proximity.
 - Discovery of application layer feature: A user of a service or social networking application is able to discover and be discovered by other users of the same service or social networking application.

In generally, D2D discovery involves three procedures, namely, signature discovery, identity discovery and verification, and service discovery. Signature discovery means

the device detection includes acquiring the transmission frame timing and synchronization of the D2D receiver with the D2D transmitter. Identity discovery and verification means the procedure that the source device can retrieve the identity of target devices through the discovered signature obtained from the discovery channel. Service discovery identifies the desired services of D2D communications after the target devices are detected and verified. The general requirements for device discovery are no doubt that all of the terminals want to be discovered fast by more neighbors with low energy consumption, whereas the legacy impact, including the additional interference to the current wide area network (WAN) and usable resource degradation caused by D2D discovery, should be minimized. Both infrastructure and ad hoc networks can be deployed for peer discovery. With the lack of network support, peer discovery in a distributed situation is time- and energy-consuming since a great deal of beacon signals and sophisticated scanning are required. Moreover, interaction signaling from higher layers between two end users will be involved to implement security procedures. Contrarily, many benefits may be obtained from the infrastructure such as synchronization, resource allocation, and interference coordination and thus make the discovery procedure more efficient. Consequently, studies on the network controlled discovery are explicitly solicited by the 3GPP study item for Rel-12 (3GPP 2013). Figures 2 and 3, respectively, illustrate the network-directed device discovery procedures and peer discovery procedures in LTE Direct.

- Interference Management: For the case of inband D2D, interference management in such a hybrid network is a critical issue in that the interference from D2D links is expected to reduce the cellular capacity and efficiency. Interference may occur when D2D devices share uplink (UL) or downlink (DL) resources with cellular systems.

Smart Device-to-Device Communication: Communication Establishment and Maintenance, Fig. 2

Network-directed device discovery procedures

Smart Device-to-Device Communication Establishment and Maintenance, Fig. 3

Peer discovery procedures in LTE Direct

- In the LTE UL, a cellular UE device sends data after several TTIs on receipt of resource allocation information from the eNB. Therefore, D2D UE may finish its RRM by using the related cellular information within these several milliseconds. Additionally, the UL is underutilized by the cellular operators comparing to DL. Thereby, most research of D2D transmission focuses on the scenario that D2D users use the uplink spectrum of an LTE system. Fig. 4 shows the near-far interference where cellular UE1 may impose serious interference to D2D transmission if they are sharing the same resource, whereas the interference from UE2 can be negligible since the long distance between the D2D pair and UE2. To arrange the dedicated

- resource for the cellular system and D2D users is an intuitive solution but leads to inefficient utilization of the available resources and low system throughput.
- In an LTE-like cellular network, since continuous control signaling and data are transmitted and fast scheduling are used in the DL spectrum, it is very difficult for the D2D transmission to share DL spectrums with cellular users. Other than the fast resource allocation, possible near-far interference is another serious problem when DL spectrums are reused, and in Fig. 5, we observe that the D2D UE1 and D2D UE2 may impose significant interference to the cellular UE1 since the short distance between them. So the key problem for sharing DL spectrums of a

Smart Device-to-Device Communication: Communication Establishment and Maintenance, Fig. 4 An example of near-far interference in the LTE uplink spectrum

Smart Device-to-Device Communication: Communication Establishment and Maintenance, Fig. 5 Near-far interference when sharing cellular downlink spectrums

- hybrid system is to avoid interference to nearby cellular UE devices.
- Many interference management methods can be utilized to coordinate the near-far interference, such as transmission mechanism design (Xu et al. 2010, 2012), power control (Xu et al. 2015, 2016), resource allocation (Xu et al. 2016), transmission mode selection (Chen et al. 2018), and so on.

related industries such as content caching, mobile commerce, mobile advertising, mobile security, and cloud services to prosperity. It is also basic and expended applications of vehicle-to-vehicle (V2V) communications and machine-to-machine (M2M) communications.

Key Applications

D2D communications are important for location-based services in current 5G networks, leading

Definitions

The Grid refers to the electric grid that can be defined as a network of several components including transmission lines, stations, and transformers aiming at delivering electricity from the power generators to end users. A Smart Grid is a system that uses two-way communication to enable bidirectional energy flows, in particular, within active distribution networks. It also enables sensing the transmission lines to achieve a more efficient electricity management.

The IEEE 2030 Standard defines a set of specifications that exploit the Smart Grid interoperability reference model and framework in power applications, DC quick charger, energy storage system, information exchange, and control through communications.

Historical Background

Energy utilities are constantly under pressure to meet the growing and complicated energy demands (Amin and Wollenberg 2005; Farhangi 2010). The traditional energy grid allows for

Smart Energy Profile 2.0

- [Smart Grid Communication Based on IEEE 2030 Standard](#)

one-way communication of energy usage between users and the utility. This does not allow utilities to have control or to suggest any changes in consumption based on the energy consumption data they obtain. In this context, the risks associated with unidirectional systems have grown and their sustainability has become a concern. These risks come with higher costs and degraded quality of service including unscheduled power outages and blackouts. To address this, smart grid systems are implemented to allow a two-way communication between the utility and its customers (Fang et al. 2012).

With advances in smart grid communications, many of the challenges discussed above have been resolved. However, given the heterogeneity of devices and protocols used in smart grid communications and the lack of interoperability between different grid's components, the need for a standard addressing these issues became apparent. To this end, IEEE has published IEEE 2030 as a standard for smart grids (IEEE 2013). Under this standard, IEEE 2030.5, also called Smart Energy Profile 2.0, defines the communication between consumers and the Utility. The standard also grants consumers the ability to manage their energy consumption. Moreover, it helps in the integration of smart devices and smart applications by defining a framework of secure and interoperable communication.

In light of the above, the details behind the implementation of a smart grid communication system compliant with the IEEE 2030 standard are given in this chapter. In what follows, an overview of the IEEE 2030 and its features is first given. Then, the implementation of the communication system in compliance with the standard is provided. After that, data analytics are illustrated as additional tools to further enhance the Smart Grid system performance.

Foundations

- Overview of the IEEE 2030 Standard and its Features

The IEEE 2030.5 standard was proposed to address the lack of interoperability in cur-

rent smart grid systems. Indeed, smart grid interoperability is a necessary foundation in order to provide seamless and end-to-end system connectivity. Smart grid interoperability is dealing with (1) power systems, (2) communications, and (3) information technology. The details behind these interoperability architectural perspectives (IAP) are given below.

- Power systems IAP (PS-IAP): The emphasis of the smart grid interoperability reference model (SGIRM) in terms of power includes apparatus, applications, and operational concepts. This perspective defines seven domains – bulk generation, transmission, distribution, service providers, markets, control/operations, and customers – to enable both traditional and alternative smart grid technology approaches in energy balance, equipment rating and optimization, and localized (distributed) control.
- Communications technology IAP (CT-IAP): The focus of SGIRM CT-IAP is communication connectivity among systems, devices, and applications in the context of the Smart Grid. The communication media between all seven domains may include wide area networks (WAN), neighborhood area networks (NAN), field area networks (FAN), and home area networks. The communications entities, wireline or wireless, stand in the system architecture, but the interfaces between two or more entities are defined as generic interconnections that establish the minimum level of interoperability. Thus, interfaces are specified in terms of performance requirement, security level, protocol layer, and other more specific needs.
- Information technology IAP (IT-IAP): SGIRM IT-IAP provides the context for information exchange interoperability among smart grid applications by the control of processes and data management flow. Designing data models represents a crucial part in structuring an information technology architecture and indicates the

intact governance process. Establishing common semantics in data model facilitates data use by multiple applications. IEEE 2030 uses a Common Information Model (CIM) from IEC 61970 and IEC 61968 to enable interoperability of the data exchanges. This happens through the use of standardized object models that provide the abstract information model (semantic), profiles for standardization (contextual), and the schemas views (syntactical). Moreover, it brings inter-application data exchange to the distributed application programming interface (API), and – within a utility’s enterprise system – of the information elements used within the smart grid infrastructure. It uses an ontology-based strategy to create and manipulate the data model, which provides easy translation and promotes interoperability by using Extensible Markup Language (XML) or Unified Modeling Language (UML). Using ontology in data model provides a formal semantics based on a shared understanding that is machine-readable.

In order to address the above interoperability features, the IEEE 2030 standard encompasses the following standards:

- IEEE Std 2030.1: Covers the technical specifications of a DC quick charger for the use of electric vehicles (EV) and original equipment maker (OEM).
- IEEE Std 2030.2: Applies SGIRM process to energy storage by emphasizing on the information relevant to ESS interoperability with EPS.
- IEEE Std 2030.3: Establishes the tests and procedures to verify if ESS meet the safety and reliability requirements of the EPS.
- IEEE Std 2030.5: This standard represents the main focus of this chapter and provides a reference document for Smart Energy Profile Protocol version 2.0 (SEP 2.0). It defines an application profile interfacing the smart grid and users enabling them to manage distributed generation, electric vehicles, energy storage, demand response, load control, and price communication. It can also be applicable in other commodities including water, natural gas, and steam.
- IEEE Std 2030.6: Presents a framework for evaluating the benefits of demand response (DR) programs and the calculation methods that would be useful in electricity market structures to provide utilities with the references for the planning and post-planning of DR programs.
- IEEE Std 2030.7: Provides technical specifications for the microgrid energy management system (MEMS). This standard addresses the technical challenges associated with the MEMS’s operation regardless of the topology and presents the control approaches required by the distribution system operator (DSO).
- Transactional smart grid (TSG) Communication Compliant with IEEE 2030.5

After discussing the need for a Smart Grid system and the importance of the standard, a real implementation of a transactional smart grid communication compliant with IEEE 2030.5 standard is discussed here. In this context, Fig. 1 represents the system model used for the communication between different Home Energy Management System Controllers (HEMSC) and Customer Agent (CA) as the primary grid edge resources (Customer domain), the transformer agent (TA) (Distribution domain), and the Utility headquarter (Transmission domain). As seen from this system architecture, CA is physically located at the customer premise near the service entrance but is administered by the utility. Since HEMSC is not trusted by the utility companies, the CA is making a firewall between the customer and distribution domains while verifying the DR action. The CA communicates with the TA to coordinate DR actions and exposes to the customers’ energy management system (EMS) a secure interface, so that both customer and utility privacy are preserved. TA communication with the utility central control room (CCR) provides centralized

Smart Grid Communication Based on IEEE 2030 Standard, Fig. 1 TSG communication system

grid condition monitoring and control. TA communication with HEMSCs via CA coordinates all DR requests and returns, and monitors the local microgrid on the low-voltage side of the transformer. The HEMSC is a residential unit responsible for control and scheduling of customer. It operates within a SEP 2.0 framework to address TA requests, based on customer choices of consumption mode, comfort level, and load priorities. The HEMSC translates data from such services to a SEP 2.0 recommended XML file for TDR purposes, including local power measurements so that DR action can be verified. It maintains customer privacy by design, acting as a customer agent to firewall any knowledge of load-specific activities and customer behavior from the TA. Moreover, Low-level DR events are initiated by the TA in response to local asset monitoring, such as transformer health.

The details behind this communication system and its compliance with IEEE 2030.5 are given in Ghalib et al. (2018) and summarized below:

- **Mesh Architecture for scalability:** In order to implement a scalable smart grid system, a Mesh architecture is selected (Akyildiz and Wang 2005; Akyol et al. 2010). This decentralized implementation does not rely on any

pre-existing infrastructure to coordinate the communication between the clients. It establishes peer-to-peer connections (Gharavi and Hu 2011). Each node in the network is connected to adjacent nodes and participates in routing by forwarding data. The determination of which nodes forward data is made dynamically based on their network connectivity. The decentralized communication model allows for a smoother self-healing process for the network. In this context, if one node drops for whatever reason, communication is rerouted through a different node.

- **Message Format and telemetry:** As per the IEEE 2030.5 standard, the format of the communicated files is XML and EXI. TAs and CAs are implemented as servers and clients to develop a RESTful communication used to exchange energy data and action requests. These messages have different function sets such as demand response and load control, load shed availability, consumption reduction negotiation, and price communication. Figure 2 describes the SEP 2.0 messaging sequence via GET commands for XML files. High-level DR events are initiated by the CCR server and are communicated to the TA. The TA communicates with individual CAs and consequently CA with

each individual HEMSCs, sending XML function sets with their corresponding elements in the sequence shown. HEMSCs send similar messages to the CA as part of the transactional negotiation and monitoring process, and CA sends likewise to the TA. In this architecture, TA and CA may both be either client or server, as required by the downstream devices. In this architecture, client issues a DNS-SD keyed by its short form device identification (SFDI) and request to locate its *EndDevice* payload, and then servers provides a DNS-SD response with URL to client. At this moment, client performs TLS and authentication and have an encrypted connection. Client GETs its *EndDevice* and server responds with the *EndDevice* resource that contains URL links to other payloads such as *RegistrationLink*, *FunctionSetAssignmentsListLink*, etc. After passing registration through *RegistrationLink*, and getting the finding assigned function via getting XML payloads by *FunctionSetAssignmentsListLink*, then the sequence of getting DR settings follows the steps illustrated in Fig. 2 starting from *DemandResponseProgramList* to *EndDeviceControl*. In response to *EndDeviceControl*, client must perform a response using *DrResponse*, which contains elements similar to those that are listed in the *EndDeviceControl*. In addition *LoadShedAvailability* addresses how long the consuming device is able to reduce consumption and at what maximum response level. In the case of an emergency, when prompt load shedding is needed, the aggregated data from this function set is helpful.

- Security Measures: Security is very critical to smart grid systems. Daily, a large amount of cyberattacks or breaches occur (Farraj et al. 2016). In 2015, an estimated 500 million personal information records were stolen or lost. The security measure taken into consideration in the

implemented smart grid communication are as follows:

Network Authentication: To protect the communication network, certain configurations can be used including unique SSIDs, static IP addresses, and passwords. The Mesh network is created after all devices boot up. The CA and TA nodes constantly look for a matched Mesh network with their static IP addresses. The TA device establishes a Mesh network under a certain SSID and excludes non-authorized IP addresses which ensures that only CAs are authorized to join the network and can communicate with other nodes in the network and prevents unauthorized entities from joining.

Encryption: A remote access feature is added to allow secure remote access using the Secure Shell protocol (SSH). While it is important to secure the end-points, it is also extremely important to secure the data flowing on the network. This is done by applying encryption using the strong asymmetric RSA with a key size of 2048. For further compliance with IEEE 2030.5 standard, TLS 1.2 is implemented.

- Security Measures: Physical protection: All TA and CAs nodes need to be well-packaged according to the IEEE 2030 standard, ensuring that they are fully protected not only from harsh weather conditions but also from theft and intruders.
- Data Analytics: After establishing secure two-way communication between different homes and the Utility as discussed above, energy consumption information is sent through this network from the CAs to the TA and then to the Utility Headquarters, as detailed in Figs. 1 and 2. Consequently, significant data may accrue at the TA which in turn relays this data to the Utility back office. Taking advantage of this

**Smart Grid

hierarchy using SEP 2.0
between TA, CA and
HEMSC for TSG

available data, analytics, and power consumption prediction are used to further enhance the performance of the implemented smart grid systems. To this end, data collected at multiple TAs is finally sent through LTE to the Cloud for storage and processing, as detailed in Fig. 3. This data undergoes aggregation and pre-processing, and is then used in forecasting. Therefore, the utility can visualize different patterns, explore and forecast energy consumption in various neighborhoods, and classify houses based on their consumption (Ahmed et al. 2018). Prediction techniques

can then be applied to forecast future consumption and identify service and asset health issues.

An example of electricity consumption forecasting is given in Fig. 4 where the energy (in Watt-hours) is predicted for the next 5 days and compared to the actual energy consumed at that time. Energy readings have been taken after every half-hour. An Autoregressive Integrated Moving Average (ARIMA) model is used for data prediction. Using the actual data, the accuracy of the prediction model is computed, and it reached 93%. The developed

ture, which can dynamically adapt network resources for services.

Historical Background

Many popular technologies appear to be contributing to the future Internet architecture. Typically, four kinds of mainstream technologies are being widely researched currently: Information Centric Networking (ICN) (Ahlgren et al. 2012), Software Defined Network (SDN) (McKeown et al. 2008), Network Function Virtualization (NFV) (Herrera and Botero 2017), and Locator/Identifier Separation Protocol (LISP) (Fuller et al. 2013). These technologies are proposed to solve the problems of current Internet from different viewpoints.

Definition

Smart Identifier Network (SINET) is a novel three layers-two domains future network archi-

- ICN: To meet users' increasing and changing demands, the communication mode should be changed from host-centric to information-centric (Xylomenos et al. 2014). ICN is based on Named Data Objects, such as web pages and videos. ICN architecture includes in-network caching and multiparty communication through replication, thus facilitating the efficient and timely delivery of information to users.
- SDN: It is proposed to decouple the control logic from data planes, enabling a logically centralized and programmable control plane. Thus, the SDN can provide more efficient configuration and higher flexibility to accommodate innovative network designs.
- NFV: It proposes to virtualize entire classes of network node functions into building blocks by evolving IT virtualization-related technologies. These virtual blocks may be flexibly connected or chained to create communication services.
- LIPS: It separates the IP address into two namespaces: Endpoint Identifiers (EIDs), which are assigned to the end hosts, and Routing Locators (RLOCs), which are assigned to the devices that make up the global routing system.

Foundations

In order to provide emerging services and improve network performance, SINET evolves to be more intelligent, dynamic, and adaptive. The network model comprises three layers, namely: *Smart Pervasive Service Layer*, *Dynamic Resource Adaption Layer*, and *Collaborative Network Component Layer*. It also contains two domains called *Entity Domain* and *Behavior Domain*. The network reference model is shown in Fig. 1.

In this architecture, the Smart Pervasive Service Layer is responsible for the naming and description of services. The *Dynamic Resource Adaption Layer* dynamically adapts network resources and builds network function-groups through perceiving service demands and network status so as to satisfy the service demands and improve the quality of experience. The *Collaborative Network Component Layer* is responsible for the storage and transmission of data. Meanwhile, the *Collaborative Network Component Layer* is also responsible for the network components' behavior perceiving and aggregation. The *Entity Domain* includes the naming of service, network function-group, and component. And the *Behavior Domain* represents the description of service, network function-group, and component. In the *Dynamic Resource Adaption Layer*, the entities in the *entity domain* are generated, according to the *behavior domain* decision, which leads to the separation of control

plane from the data plane in SINET (Zhang et al. 2016).

At the same time, smart and collaborative functions have been designed into the *Smart Pervasive Service layer* and *Collaborative Network Component layer* to interact with the *Dynamic Resource Adaption layer*. With these enhanced functions, SINET can achieve the decoupling of the three bindings thoroughly. With these features, SINET further resolve the scalability, mobility (Zhang et al. 2015), security, and controllability issues which have been partially solved in SINET fundamental model. Furthermore, SINET can solve the problem of resource utilization, energy efficiency, and support of cloud computing and big data transmission.

As shown in Fig. 2, *Service Identifier (SID)* is introduced as a unique and independent namespace to name a smart service in Entity Domain, which is used to separate the resource and location of services. *Function-group Identifier (FID)* is used to name a network function-group. *Node Identifier (NID)* (Luo et al. 2014) is used to name a network component device. The Entity Domain leverages FID and NID to avoid the “control and data binding.” In the Behavior Domain, *Service Behavior Description (SBD)*, *Function-group Behavior Description (FBD)*, and *Node Behavior Description (NBD)* are used to provide further description of SID, FID, and NID, respectively. They are widely used in the enhanced mapping process in SINET which is shown in the following. Three intelligent mapping functions are proposed, namely: F1, F2, and F3. F1 chooses the appropriate network function-groups according to the service demands. F2 matches the network components of a network function-group with the service demands. F3 achieves the behavior aggregation of network components by using intra-function-group cooperation mechanism (Guan et al. 2017).

By applying the above mechanisms, emerging service types are supported with high efficiency, the utility ratio of network resource is improved, and the energy consumption of network is reduced.

Smart Identifier Network, Fig. 2

Enhanced mapping models

Key Applications

Smart Identifier Network (SINET) is a specific instance of innovative networking architecture, which can promote the deployment of collaborative vehicular edge computing (Wang et al. 2018). SINET can easily accomplish optimal decision, task allocation, and resource dynamic scheduling through managing network function groups logically and can solve the problem of resource utilization, energy efficiency, and support for cloud computing and big data transmission.

Intelligent metering system

Definition

Smart Metering describes an application which allows remotely determining the consumption of electricity in a household or enterprise by means of a communication network. Beyond the mere meter reading, a smart meter may also allow for the remote control of generators and consumers of electrical energy, so-called distributed energy resources (DER). Smart Metering enables a number of services related to the operation of energy systems, so-called Smart Energy Markets (e.g., dynamic pricing, demand response) and Smart Energy Grids (e.g., monitoring and control). The concept of Smart Metering also includes other utilities, such as water, gas, and district heating.

Historical Background

The introduction of electronic and networked electricity meters, which can be read remotely, was initially motivated by cost saving potential and expected process efficiency gains: a meter with connectivity enables the utility to determine the consumption at any point in time without having to send a person to the location of

the meter, which is often not accessible without prior arrangement. At the same time, information about the energy usage can be made available to the consumer in more frequent time intervals in order to raise the awareness of the energy used to eventually motivate energy-saving behavior. A Smart Meter may also enable utilities to reduce or even switch off the energy supply remotely (e.g., in case the contract with a consumer is terminated). First-generation Smart Metering systems have been implemented in various countries on different scales using different communication technologies, including wireless technologies (Lichtensteiger et al. 2010). The largest Smart Meter rollout took place from 2001 to 2009 in Italy, where over 30 million Smart Meters were connected using primarily narrowband power line communications (PLC).

With the fundamental changes in the overall architecture of the energy system in terms of energy market deregulation and increased share of renewables to reduce carbon emissions, Smart Metering has become an important enabler to implement advanced:

- **Smart Market** mechanisms (e.g., automated control of household appliances based on dynamic pricing depending on the availability of renewable energy)
- **Smart Grid** control (e.g., stability monitoring and control of the electricity grid in case of increasingly highly distributed and volatile energy production from distributed renewable energy sources)

Those second-generation Smart Metering systems require a higher communication performance in terms of data rate, response times, and capacity. Therefore a number of communication options are being discussed, including wireless networks (Wietfeld et al. 2011). In some regions the rollout of Smart Meters has been mandated by dedicated regulation, for example, in the European Union, a corresponding directive mandates that 80% of consumers shall be equipped with intelligent metering systems by 2020 (European Parliament 2012).

Requirements and Challenges

A Smart Metering application (see Fig. 1 for a high-level architecture overview) typically comprises the *Smart Meters* installed at the households which are mainly consumers of electrical energy but to an increasing amount may also be producers, e.g., by photovoltaic (PV) modules. The Smart Meters are highly embedded, electronic systems of a size similar to traditional meters to fit in the original installation. They account the exact amount consumed and produced energy with a given resolution. The *Smart Meter operator* collects the information in the back end and provides interfaces to Smart Market and Smart Grid control instances. The resolution of the metering information is not only defined by technical boundary conditions (e.g., amount of storage memory), but may also take into account privacy concerns of the consumers (Finster and Baumgart 2015).

A key element of Smart Meters are their *networking capabilities*: on the one hand, the metering information is delivered via wide-area communication to the accounting system of the utility to produce an accurate bill; on the other hand, the current and accumulated

metering information may also be displayed to the consumer, either via a locally connected device or via a smartphone app via the Internet. Additionally, the Smart Meter for electricity may also be connected to meters of other utilities (multi-utility) and/or distributed energy resources (DER) such as remotely controllable household appliances. Advanced Smart Meters may also monitor parameters of the energy systems, such as phase or frequency of current or voltage. Finally, the Smart Meter may even execute switching actions with DERs necessary to preserve the stability of the energy grid, e.g., by taking a PV module of the grid to prevent a critical overload or start the charging of an electric vehicle to take load off the grid.

From this wide range of potential services associated with Smart Meters, it becomes apparent that the *IT security requirements* play an important role when implementing a Smart Metering system: the coordinated attack on a large fleet of Smart Meters is considered to be a severe risk for the stability of the energy system, as energy loads may be manipulated to even physically harm the overall energy grid (McDaniel and McLaughlin 2009).

Smart Metering, Specific Challenges, and Solution Approaches, Fig. 1 High-level architecture of Smart Metering application

The *wide-area communication requirements* of Smart Meters can be described by the following parameters:

- **Location:** meters are often located in areas of the house, which are not a primary focus for providing network connectivity. Depending on country-specific preferences and tradition, meters may be located outside of buildings (e.g., in the USA) but also indoor and even in basements, requiring a so-called deep indoor coverage (e.g., in Germany and other European countries). Ideally, an existing meter can be simply replaced by a Smart Meter reusing the same installation location without further wiring, thereby creating a minimum of effort on the end consumer side.
- **Size of data packets:** there are different standardized protocols which describe the detailed message formats associated with Smart Metering services (Feuerhahn et al. 2011). While in regular operation, the size of the data packets related to metering and monitoring is small (kB range), in case of firmware updates, 10+ MB of data need to be transferred.
- **Latency:** within the distribution network, the latency requirements are in the range of seconds rather than ms and therefore less harsh than in the high-voltage network or other vertical industry areas (e.g., autonomous driving). To produce accurate time stamps, the latency of the communication link needs to be below a certain threshold in case a synchronization with network-based time sources is implemented (Mills 1991).
- **Network capacity:** following the abovementioned IT security concerns, the network needs to provide a sufficient capacity to handle encrypted data, as well as operate secure and authenticated connections (e.g., Transport Layer Security). Unlike the end user-driven communication traffic, Smart Meter communication traffic does not have an inherently stochastic nature, but can be controlled by the operator of the Smart Metering system. Through suitable scheduling, it can be avoided that different

Smart-Meter-related services are initiated in parallel and lead to overload situations within the communication network. If, for example, the Smart Meters shall deliver metering information in 15-min intervals, a corresponding system design can ensure an even spread of the transmission of the metering information within a network section in which the Smart Meters compete for the same network resources.

- **QoS guarantees:** in contrast to best effort consumer services, Smart Meter services need to be executed with guaranteed performance, for example, a system-critical firmware update necessary to fix severe security threat needs to be delivered to all Smart Meters within the shortest possible time frame. Due to security considerations, each update may need to be authenticated and executed individually, leading to a significantly higher network load than in times of regular operation. As a consequence, the wide-area communication system to support Smart Meters needs to provide effective prioritization and resource management.

The standard Internet connection of the end consumer – may it be based on Digital Subscriber Line (DSL), broadband cable, or fiber – is typically considered not to be suitable for advanced Smart Metering communication traffic, as it is not owned and controlled by the Smart Meter operator. Therefore dedicated network connectivity solutions are needed to implement Smart Meter infrastructures. The specific challenge lies in accessing the households through an appropriate access network (AN) or more specifically neighborhood area network (NAN). While first-generation automated meter reading systems have been to a large extent based on PLC infrastructures, wireless systems have been also considered an option for Smart Meters from early onwards. Reusing the power supply line for communication is attractive for utilities and especially broadband powerline communications is a viable option for Smart Metering systems. Yet electromagnetic interferences between PLC and

the power system may impact the performance of the communication link (Ahmed and Lampe 2013). Wireless networks offer the flexibility to be operated independently of the power grid and the end consumers' communication network. Still they can provide connectivity for the Smart Meter without further wiring inside the consumers building.

Solution Approaches Based on Wireless Networks

Smart Meter communication infrastructures may be realized as dedicated utility-specific wireless networks, and they may leverage public network infrastructures. In the following example solution approaches are described.

Cellular Networks

Data services of cellular networks are suited to fulfill the requirements for Smart Metering applications to different degrees:

- **Operating frequencies:** As a general rule of wireless networks, a lower frequency is associated with less attenuation and therefore better coverage. In particular when it comes to deep indoor penetration, networks operated at *subGHz frequencies* have significant advantages over networks operated at higher frequencies (Hägerling et al. 2014). While until recently GSM/GPRS/EDGE operated at 900 MHz was used to support first Smart Meter installations, LTE operated at subGHz (at 700 MHz and 800 MHz) has become a preferred wireless networking choice for the most recent generation of Smart Meters. UMTS is – due to its higher carrier frequency in the GHz range – not suited to meet the coverage expectations of Smart Metering services.
- **National roaming:** Due to varying basement construction and materials, coverage of 100% is difficult to achieve even for subGHz frequencies. A hybrid approach combining power line communication to provide connectivity to a difficult-to-reach basement

with a wireless connection at the PLC concentrator is one option. But by combining multiple cellular networks with partially complementary coverage, the overall coverage can be enhanced as well (Wäfler and Heegaard 2015). While multi-homing approaches involving multiple contracts and SIM cards are costly, international SIM cards provide national roaming capabilities and enable a flexible association with alternative networks. National roaming is usually not supported as standard feature due to regulatory constraints, yet it can be easily supported by introducing SIM cards issued in another country. Based on associated roaming agreements, the access to any available cellular network is enabled. Studies show the benefit of national roaming for critical infrastructures (Mattioli and Dekker 2013).

- **QoS guarantees:** Although prioritization options have become technically available by *IMS* (IP-based Multimedia Subsystem)-enabled policy control function, service providers do not yet provide service guarantees to third parties. With the future adoption of *network slicing technologies* (Rost et al. 2017) and software-defined networking (Dorsch et al. 2014) for public 4G and 5G cellular networks, exclusive network resources can be offered to Smart Meter operators to allow for the management of resources as if they were operating their own network.
- **Machine-type communications:** While *GPRS/EDGE machine-to-machine communications* is an option for early Smart Meter deployments with limited penetration, there are network capacity limitations in case of higher penetration rates and advanced security requirements (e.g., fast firmware upgrades requiring higher bandwidths). Therefore *LTE*-based deployments are considered to be a sustainable solution approach, addressing both capacity as well as QoS requirements. Recent additions to LTE addressing specifically *machine-type communications* eMTC (evolved machine-type communications) and NB-IoT (narrowband Internet of things) are of

interest in the context of Smart Metering, as they allow for cost-efficient modems using lower bandwidths and provide so-called *extended coverage* operation modes. But the extended coverage modes need to be carefully chosen as the improved coverage needs to be traded with lower spectrum efficiency, lower data rate, and significantly higher latency (Liberg et al. 2018).

- **Networks at 450 MHz:** While the CDMA-based UMTS technology has been identified as not ideally suited for Smart Metering due to its typical operating frequencies, the alternative third-generation mobile network technology CDMA-2000 has been adapted to **450 MHz** and has been implemented as dedicated communication network for utilities (Nedevschi et al. 2007). The focus of those CDMA-450 networks is usually on system-critical Smart Grid operations but may also include Smart Metering applications. As LTE can also be operated in a 450 MHz band, it can be expected that LTE-450 will gradually replace CDMA-450 installations as fourth-generation mobile networking technology.

Wireless Mesh Networks

While cellular wireless networks are certainly a viable option for Smart Metering applications, also alternative wireless technologies have been proposed. The drivers for those alternatives are the operation in less costly or even *license-free frequency bands* and the use of cost-efficient system technology, which spare unnecessary functionalities such as mobility support. The solution options range from short-range systems which just bridge the distance between household and the road to allow for collection of metering data by a bypassing vehicle to mesh networks which provide wide-area coverage similar to cellular networks, but with a dedicated focus.

Various *proprietary* (Lichtensteiger et al. 2010) as well as *standardized* wireless mesh technologies, for example, IEEE 802.15.4 (Fadlullah et al. 2011) and IEEE 802.11 (Böcker et al. 2017), have been proposed in recent years and implemented in various scenarios.

As the operation in unlicensed bands is typically restricted in terms of transmit power and duty cycle, those technology options have been particularly been successful in markets where outdoor coverage is sufficient. Leveraging *relay functionality* is essential for extending the coverage; at the same time, capacity bottlenecks need to be avoided by careful network planning.

For advanced Smart Metering applications supporting system-critical functionality, the operation in unlicensed bands, although it may be less costly, does often not fulfill the requirements of a critical infrastructure operation regarding QoS (Böcker et al. 2017).

Conclusions and Outlook

Smart Metering is an enabler for the automation of the energy system to support Smart Market and Smart Grid services. It is key example of a new class of vertical applications with challenging performance requirements regarding scalability and QoS guarantees. As result of region-specific requirements and boundary conditions, different wireless solution options for Smart Metering systems are viable.

Social group utility maximization

Definition

Social group utility maximization (SGUM) for cooperative wireless networking takes into account both social relationships and physical coupling among users. Specifically, instead of maximizing its individual utility or the overall network utility, each user aims to maximize its social group utility that hinges heavily on its social tie structure with other users. This framework provides rich modeling flexibility and spans the continuum between noncooperative game and network utility maximization (NUM) – two traditionally disjoint paradigms for network optimization.

Historical Background

Mobile networks have been projected to continue growing rapidly in the foreseeable future. Different from other networks (e.g., sensor networks), a distinctive characteristic of mobile networks is that mobile devices are carried and operated by human beings. With the explosive growth of online social networks such as Facebook and Twitter, more and more people are actively involved in online social interactions, and social relationships among people are hence extensively broadened and significantly enhanced. Then it is natural to ask whether “social relationships” among mobile users can impact the communications and interactions among their devices, and if yes, how can the

social structure be cleverly leveraged? With this insight, as illustrated in Fig. 1, a mobile network is viewed as an overlay/underlay system where a “virtual social network” overlays the physical communication network (the “social network” is virtual, in the sense that the social tie structure therein results from existing human relationship and online social networks) and leverages the intrinsic social tie structure among mobile users to facilitate cooperative wireless networking.

With this motivation, a novel *social group utility maximization* (SGUM) framework is advocated to take into account both the users’ social relationships and physical coupling. As illustrated in Fig. 1, a key observation is that users are coupled not only in the physical domain due to the physical relationship (e.g., interference) but also in the social domain due to the social ties among them. It would be a win-win case for users to help those users having social ties with them. Specifically, the distributed decision-making problem for cooperative networking among users is casted as a SGUM game, where each user maximizes its social group utility, defined as the sum of its own individual utility and the weighted sum of the utilities of other users having social tie with it (Chen et al. 2014, 2015, 2016).

SGUM Framework

Physical Network Graph Model

A set of wireless users $\mathcal{N} = \{1, 2, \dots, N\}$ is considered where N is the total number of users.

Social Group Utility Maximization, Fig. 1 An illustration of the social group utility maximization framework. In the physical domain, users have different physical cou-

pling subject to physical relationships (e.g., interference). In the social domain, users have heterogeneous social coupling due to the social ties among users

The set of feasible strategies for each user $n \in \mathcal{N}$ is denoted as $\mathcal{X}_n$. For instance, a strategy $x \in \mathcal{X}_n$ can be choosing either a channel or a power level for wireless transmissions. Subject to heterogeneous physical constraints, the strategy set $\mathcal{X}_n$ can be user-specific. For example, the strategy set $\mathcal{X}_n$ can be a set of feasible relay users that are in vicinity of user n for cooperative communication.

To capture the physical coupling among the users in the physical domain, the *physical graph* $\mathcal{G}^p = \{\mathcal{N}, \mathcal{E}^p\}$ is introduced (see, e.g., Fig. 1). Here the set of users $\mathcal{N}$ is the vertex set, and $\mathcal{E}^p \triangleq \{(n, m) : e_{nm}^p = 1, \forall n, m \in \mathcal{N}\}$ is the edge set where $e_{nm}^p = 1$ if and only if users n and m have physical coupling, i.e., users n and m can affect each other's payoff by taking some actions. For example, two users have the physical coupling if they can cause interference to each other when using the same channel for data transmission. Then the set of users that have physical coupling with user n is also denoted as $\mathcal{N}_n^p \triangleq \{m \in \mathcal{N} : e_{nm}^p = 1\}$.

Let $\mathbf{x} = (x_1, \dots, x_N) \in \prod_{n=1}^N \mathcal{X}_n$ be the strategy profile of all users. Given the strategy profile $\mathbf{x}$, the individual utility function of user n is denoted as $U_n(\mathbf{x})$, which represents the payoff of user n , accounting for the physical coupling among users. For example, $U_n(\mathbf{x})$ can be the achieved data rate or the satisfaction of quality of service (QoS) requirement of user n under the strategy profile $\mathbf{x}$. Note that in general, the underlying physical graph plays a critical role in determining the individual utility $U_n(\mathbf{x})$. For example, users' achieved data rates are determined by the interference graph and channel quality.

Social Network Graph Model

The social graph model is next introduced to describe the social ties among users. The underlying rationale of considering social ties is that the handheld devices are carried by human beings and the knowledge of human social ties can be utilized to enhance the performance of cooperative networking.

Specifically, the *social graph* $\mathcal{G}^s = \{\mathcal{N}, \mathcal{E}^s\}$ is introduced to model the social ties among the users. Here the vertex set is the same as

the user set $\mathcal{N}$, and the edge set is given as $\mathcal{E}^s = \{(n, m) : e_{nm}^s = 1, \forall n, m \in \mathcal{N}\}$ where $e_{nm}^s = 1$ if and only if users n and m have social tie between each other, which can be kinship, friendship, or colleague relationship between two users. Furthermore, for a pair of users n and m who have a social edge between them on the social graph, the strength of social tie is formalized as $w_{nm} \in [0, 1]$, with a higher value of w_{nm} being a stronger social tie. User n 's *social group* $\mathcal{N}_n^s$ is defined as the set of users that have social ties with user n , i.e., $\mathcal{N}_n^s = \{m : e_{nm}^s = 1, \forall m \in \mathcal{N}\}$.

Based on the physical and social graph models above, users are coupled in the physical domain due to the physical relationships and also coupled in the social domain due to the social ties among them. It would be a win-win case for users to help those users having social ties with them. With this insight, the *social group utility* of each user n is then defined as

$$S_n(\mathbf{x}) = U_n(\mathbf{x}) + \sum_{m \in \mathcal{N}_n^s} w_{nm} U_m(\mathbf{x}). \quad (1)$$

It follows that the social group utility of each user consists of two parts: (1) its own individual utility and (2) the weighted sum of the individual utilities of other users having social ties with it. In a nutshell, the social group utility function captures the feature that each user is socially aware and cares about the users having social ties with it.

Social Group Utility Maximization Game

The distributed decision-making problem among the users is then considered, aiming to maximize their social group utilities. Let $\mathbf{x}_{-n} = (x_1, \dots, x_{n-1}, x_{n+1}, \dots, x_N)$ be the set of strategies chosen by all other users except user n . Given the other users' strategies $\mathbf{x}_{-n}$, user n wants to choose a strategy $x_n \in \mathcal{X}_n$ to maximize its social group utility, i.e.:

$$\max_{x_n \in \mathcal{X}_n} S_n(x_n, \mathbf{x}_{-n}), \forall n \in \mathcal{N}.$$

Social Group Utility Maximization, Fig. 2 Network optimization with different users' social awareness levels

The distributed nature of the problem above naturally leads to a formulation based on game theory such that each user aims to maximize its social group utility. The decision-making problem among the users is thus formulated as a strategic game $\Gamma = (\mathcal{N}, \{\mathcal{X}_n\}_{n \in \mathcal{N}}, \{S_n\}_{n \in \mathcal{N}})$, where the set of users $\mathcal{N}$ is the set of players, $\mathcal{X}_n$ is the set of strategies for each user n , and the social group utility function S_n of each user n is the payoff function of player n . The game Γ is called as the SGUM game, and the concept of *socially aware Nash equilibrium* (SNE) is defined as follows:

Definition 1 A strategy profile $\mathbf{x}^* = (x_1^*, \dots, x_N^*)$ is a socially aware Nash equilibrium of the SGUM game if no player can improve its social group utility by unilaterally changing its strategy, i.e.:

$$x_n^* = \arg \max_{x_n \in \mathcal{X}_n} S_n(x_n, x_{-n}), \forall n \in \mathcal{N}.$$

It is worth noting that under different social graphs, the proposed SGUM game formulation can provide rich flexibility for modeling the network optimization problem (as illustrated in Fig. 2). When the social graph consists of isolated nodes with $w_{nm} = 0$ for any $n, m \in \mathcal{N}$ (i.e., all users are selfish), the SGUM game degenerates to the noncooperative game formulation. When the social graph is fully meshed with edge weight $w_{nm} = 1$ for any $n, m \in \mathcal{N}$ (i.e., each user is fully altruistic and cares enough about other users), the SGUM game becomes the network utility maximization problem, which aims to maximize the system-wide utility. The SGUM framework in this study is applicable to general social graphs and hence can bridge the

gap between noncooperative game and network utility maximization – two traditionally disjoint paradigms for network optimization.

Due to its rich modeling flexibility, the SGUM framework has been widely applied in many networking issue studies, such as power control, random access control, spectrum access, computation offloading, data caching, and wireless jamming (Chen et al. 2016; Gong et al. 2014, 2017, 2015; Tang et al. 2016; Zhu et al. 2017).

Social network service and the Internet of things

Definition

The Social Internet of Things is a social network that includes the Internet of Things, allowing you to share services with others through social networks. Each Internet of Things (IoT) contains a number of technologies, including being able to search each other's Internet resources through social networks and work with your online neighbors to achieve common goals.

Historical Background

Social Network

The structure of a social network (Scott 2017) is premised on a network structure (Ray and

Bill 2003) formed by the relationships between many nodes. People or organizations are like nodes, and social relations represent the connections between these nodes. There are social interactions between people or people and organizations, and these interactions create connections that link people or organizations together to form social networks. The development of social networks started from the rise of the e-mail period, and with the progress of the Internet, social networks have gradually transformed into other areas: the family site period, instant messaging period, dating period, and the blog period, to the current period of social network services (Danah and Nicole 2007). Social networks create extremely virtual and realistic human interactions on the Internet.

Internet of Things

The Internet of Things (IoT) (Jayavardhana et al. 2013) aims to enable all types of communication on the Internet. All ordinary objects that can perform independent functions can be connected through the network. Connections are made device to device through Bluetooth, ZigBee, RFID, and other information sensing technology (Lionel et al. 2004; Jin-Shyan et al. 2007), enabling all devices to connect to the network. Through communication and information exchanges, all devices become conscious and intelligent. As the number of smart devices increases, so too does the amount of data moving between devices. In order to manage the installation and use the information more effectively, the Social Internet of Things (SIOT) (Luigi et al. 2012) is generated. By combining many social networking groups, SIOT is able to combine a large amount of data to provide more accurate answers to complex questions. And because SIOT uses social connections in social networks, the IoT can build larger social relationships with more devices. SIOT offers a wider range of smarter applications than IoT does (Luigi et al. 2014).

There are five relationship types in SIOT (Luigi et al. 2014): parental object relationship (POR), co-location object relationship (C-LOR), co-work object relationship (C-WOR), ownership

Social Internet of Things, Table 1 The architecture schematic of SIoT

Relationship type	Relationship rule	Communication type
Parental object relationship (POR)	There is a connection between the same devices made by the same manufacturer	M2M, D2D
Co-location object relationship (C-LOR)	The connection between people or devices in the same place	M2M, H2M, M2H, H2H, D2D
Co-work object relationship (C-WOR)	A collaboration object that is created when the same kind of IOT application is coshared	M2M, H2M, M2H, D2D
Ownership object relationship (OOR)	Same appliance with multiple users	H2M, M2H
Social object relationship (SOR)	The social behavior between people in life generates connections on the device	H2H, M2M, D2D

object relationship (OR), and SOR (SOR). The five relationship types are described in Table 1.

Four different communication types are used in SIoT's five relationship types: human to human (H2H), machine to machine (M2M), human to machine (H2M), and machine to human (M2H). H2H refers to a person's communication behavior after establishing a social relationship. M2M refers to devices that can communicate directly with each other over a wired or wireless network. In the M2M there is more developed D2D technology. D2D (Ometov et al. 2016) refers to direct communication between two mobile communication devices. H2M signifies communication between a person and a device. The device is an auxiliary tool controlled by the operator. M2H means that the device sends a notification to a person when an event on the device triggers a conditional alarm.

Architecture of SIoT

The components of SIoT can be divided into four parts (Ali 2015). The first part is the actor which includes humans and IoT devices. Both of these can manage data by sending data and receiving control information. The second part is an intelligent system, which is used to manage and consort interactions between different actors. The third component of SIoT is the interface; its main function is to provide an interface which enables the actor to input and query data. The fourth component is the Internet that can connect actors anywhere at any time. Finally, the communication medium is also an important part for SIoT, so that the service of a smart device can be offered to users through Wi-Fi (Huang et al. 2017), mobile communication (Al-Turjman 2017), and so on. Among these components, the intelligence system is a key technology, which can build relationships between each actor, provide suitable access permission for different groups, and discover the relationships between different groups. Atzori et al. (2012) proposed the structure of an intelligence system which included identity management, owner control (OC), relationship management (RM), service discovery (SD), service composition (SC), and trustworthiness management (TM). The architecture schematic of SIoT is shown in Fig. 1.

Grouping

Among these components, SD and SC are the first and most critical steps to build relationships among different actors and to compose them together. Many technologies are used to discover the relationship between actors by enhancing semantic reasoning for greater context awareness (Maarala et al. 2017). Shen et al. (2017) adopt the semantics of a top-k query to search the optimal SIoT group objects. Kang et al. (2016) proposed a grouping method based on social correlations and the consistence of the groups according to similar node information. Gil et al. (2016) summarized the context aware method of SIoT, which includes information retrieval (IR) (Rau et al. 2015), infor-

Social Internet of Things, Fig. 1 The architecture schematic of SIoT

Social Internet of Things, Table 2 Analysis of communication type of SIoT works

information extraction (Zhao et al. 2015), and a search engine for the Web of Things (Romer et al. 2010). It can be seen that the semantic reasoning is an important technology for SIoT, which facilitates data integration and interoperability in SIoT applications (Barnaghi et al. 2012). Table 2 is an analysis of communication types of SIoT works.

Key Applications

In order to satisfy and realize the demand for people and things to exchange their data or infor-

mation in SIoT, the deployment of IoT devices, through the information platform to exchange their information or integrate the data and using Web service or API, is required. But, in the application of SIoT, the following details must be noticed (Victoria et al. 2014): (1) the users can know their personal information and can update their status or delete it; (2) when users want some information they find interesting, they can get this information from IoT devices; (3) the users have the ability to change the status of the things/devices, e.g., using the smartphone to control the lights in their home; and (4) finally, the application should provide a trigger rule, so users have the ability to easily set the rule. Due to the fact that the goal of SIoT is to facilitate the relationships between people and things, and it may help to make the IoT smarter, there is much relevant literature and application services focus on it (Table 3).

In regard to agriculture, Abdullah and William (2016) suggest using the IoT devices to help farmers collect data; through these services, they can then share information with other farms. In the smart home (Dina et al. 2013), the IoT device deployments are targeted at household appliances and can gather information, like the temperature

Social Internet of Things, Table 3 The application of SIoT

	Application	Literature	Communication type	Common relationship type
Consumer	Smart home	Dina et al. (2013)	H2M, M2M, D2D	C-LOR, OOR, SOR
	Smart shopping	Ugo et al. (2011)	M2H, H2H	OOR, SOR
	e-health	Chaitali et al. (2016)	H2H, D2D	POR, SOR
	Gastronomy/tourist	Luca et al. (2013)	M2H, H2H	OOR, SOR
Enterprise	Infrastructure monitoring	Anderson et al. (2017)	M2H	POR, C-WOR, SOR
	Transportation	Augusto et al. (2018)	M2M, D2D	C-LOR, C-WOR, SOR
	Education	Anmol and Pradeep (2016)	H2M	C-LOR, OOR, SOR
	Agricultural	Abdullah and William (2016)	M2H, D2D	C-LOR, OOR, SOR

in a room, or it serve as an alarm for emergency situations. People can use the SIoT service to shop for interesting things (Ugo et al. 2011) and find the information required with their smart-phone. Of course, it can also be used to help the tourism industry (Luca et al. 2013). Finally, these application services can be combined with others, like transportation and infrastructure monitoring, and become part of a smart city (Panagiotis et al. 2013). Anmol and Pradeep (2016) proposed its use in the school environment to help teaching and learning. It may also be used to enhance the relationships between people and things. On the other hand (Luigi et al. 2014), since smart shopping changes the habits of consumers and markets, many enterprises have been employing this application service and specifically designing products to service the consumer.

efficiency of service development in an OS is a significant challenge in SIoT (Gubbi et al. 2013). In the SIoT, IoT devices include different service types; however, the service working time is based on the capacity of the battery. Highly complex interactions will make these IoT devices run out of energy quickly. (4) **Security:** The security challenges that include privacy, trustworthiness, and integrity of data are at risk in three ways (Eagle et al. 2006). The first is third-party access to data; the second is collector use and distribution of data; and the third is when data are mixed with other data. SIoT aims to build relationships between friends in order to reduce the communication cost. The security issues of data security, data theft protection, and network attacks among different SIoT groups remain challenges that SIoT must overcome.

Challenge of SIoT

There are some derivative challenges intrinsic to the development of SIoT. (1) **Compatibility:** Seeking the compatibility of heterogeneous devices from different vendors, a standard operating system (OS) must necessarily be developed because certain applications need to interoperate with each other (Ahmed et al. 2016). (2) **Accuracy and Reliability:** For sensitive SIoT applications, such as vehicle to vehicle, ensuring accuracy and reliability is a challenge for SIoT. Thus, a highly precise system is needed (Afzal et al. 2017). (3) **Energy Efficiency:** The energy

Social cooperation system

Definition

Social IoT crowd-sourcing regulates users on the social network that used to publish useful information to cooperate a common task.

Historical Background

Social Internet of Things (SIoT) is a special type of IoT which provides users with fast and convenient information dissemination based on the connection of social network environment (Serrat; Atzori et al. 2012). Various kinds of data can spread rapidly through the social network (Houston et al. 2014). Users can share information as a post based on what they see and hear. When a disaster happened, people in the disaster area usually use a mobile phone to publish the disaster information with the picture to the social network. When other people see the disaster information, they usually leave a comment or upload the new information to the social network (Houston et al. 2014). The people

who proactive publish the disaster information on the social network, we called that is citizen cooperation. The citizen notification is the useful to gather the disaster information during disaster response state. And a tool with map is necessary to recruit people to gather disaster information.

The Crowd-Sourcing System (Prpića et al. 2015; Zhao and Zhu 2014) is a mode of information acquisition. Some unspecified users on the Internet collaborate on a certain task to provide information to meet the common task (Karger et al. 2014). Each user only contributes a small amount of effort (time, information, etc.), and the entire system will gather a large amount of information. This mode can provide diversity, immediacy, and scale information (Xu et al. 2016; Lina et al. 2018). However, this approach requires many spontaneous users. Thus, we propose the citizen cooperation map to recruit users and gather the disaster information.

Disaster Reduction Application

The 2010 Haiti earthquake was a magnitude 7.0 earthquake (2010 Haiti earthquake). The government has no a GIS system to integrate the disaster information. And the foundation map has not been updated for 20 years. The OSM's Humanitarian OpenStreetMap Team (HOT) spent seven days conducting field surveys and mapping by volunteers on the Internet. The map (Fig. 1) completed in a week has become an important basis for disaster relief (2010 Haiti earthquake damage map).

Many people in the disaster area use Twitter to exchange information because of the lack of telephone communications. They publish first-hand disaster information through social networks. In addition, users all over the world donate materials through social websites such as Twitter and Facebook.

The typhoon Haiyan invades Philippines on 2013 (Typhoon Haiyan). The International Red Cross humanitarian aid organization immediately rushed to the disaster area to assist with disaster relief and recovery work, but encountered the plight of the lack of local maps. Launched by the

Humanitarian OpenStreetMap Team and assisted by 410 international OSM volunteers, the basic maps (Fig. 2) of the disaster area were quickly established to provide on-site rescue organization personnel (Typhoon Yolanda Map).

During the Typhoon Haiyan, the GDG Philippines, GBG Philippines, and other nongovernmental community groups in the Philippines jointly issued a Google Crisis map (Fig. 3) to annotate disaster warning areas and material distribution areas (Typhoon Haiyan/Yolanda Crisis and Relief Map). The two examples in the above are mainly initiated by professional organizations, and the relief agencies are responsible for integrating first-hand information on the disaster.

The Typhoon Nepartak landed at Taimali Township, Taitung County, around 5:50 on July 8 and left Taiwan at 14:30 (Typhoon Nepartak 2016). The actual time to influence Taiwan was July 8. The administrator of the group of Facebook-台東臉書災害通報 used the group as a temporary disaster collection center and called on members to actively provide the latest disaster information. One of the members even establishes a collaboration map to let users upload disaster information (Fig. 4).

Base on the concept of social Internet of Things, the citizen cooperation map (Fig. 5) is established by the National Science and

Technology Center for Disaster Reduction (NCDR). It provides users upload the disaster information with web interface during disasters. The user clicks on the map to locate the location, pick up the disaster category, write related descriptions, and upload photos to complete the disaster report (Fig. 6).

The citizen cooperation map uses Facebook-like publishing approach to share disaster information. It is more intuitive to use. In addition to collecting disaster information reported by users, the map can also share the information to Facebook and Google+ for friends or family.

Through citizen cooperation map, disaster prevention personnel of government can extract disaster information into Web-GIS based map. The main purpose of building this map is to provide high-quality information to the commander of center emergency operation central (CEOC) (Fig. 7).

Conclusions

Due to popularity of mobile devices and the development of the Internet, people exchange information through social networking sites has become more frequent. When a disaster occurs, disaster information can be quickly and massively transmitted. The web map is good tools to recruit people to gather disaster information

effectively from social network. That disaster information can be immediately gathered for disaster response task to assist the disaster response task.

Definition

Space-time block codes are coding and modulation schemes for multi-input multi-output wireless communication systems which map information bits into multidimensional signals to be transmitted by multiple transmit antennas.

Historical Background

In the 1990s, a revolutionary theoretical work revealed that multi-input multi-output (MIMO) wireless communications can provide substantial capacity increase in rich scattering and reflection environments compared to conventional single-input single-output (SISO) systems (Telatar 1995; Foschini and Gans 1998). Then, performance analysis for MIMO systems with practical signal transmissions and receiver detection/decoding was carried out in Guey et al. (1999), Tarokh et al. (1998) in which two design criteria (one related to coding gain and one related to diversity order or degree of redundancy) were proposed for space-time (ST) signal/code designs in order to minimize the MIMO transceiver error probability. Following the two code design criteria, in the late 1990s and early 2000s, a large number of works on ST signal/code designs were published in literature including orthogonal ST block codes (Alamouti 1998; Tarokh et al. 1999; Ganesan and Stoica 2001; Tirkkonen and Hottinen 2002; Su and Xia 2003; Su et al. 2004), quasi-orthogonal ST block codes (Jafarkhani 2001; Sharma and Papadias 2003; Su and Xia 2002, 2004), cyclic ST block codes (Hochwald and Sweldens 2000; Hughes 2000), unitary ST block codes (Hochwald and Marzetta 2000; Hochwald et al. 2000; Shokrollahi et al. 2001; Hassibi and Hochwald 2002), algebraic ST block codes (Damen et al. 2002; Damen and Beaulieu 2003; Xin et al. 2003), Golden code (Belfiore et al. 2005), perfect ST block codes (Oggier et al. 2006), and so on. Some survey on various STBC code designs and performance comparisons can be found in the books (Larsson and Stoica 2003; Liu et al. 2009) and the references therein. Note that MIMO

technology with STBC has been used in various wireless communication systems including WiFi local area networks and 4G wireless cellular networks.

Foundations

MIMO wireless communication systems with multiple transmit antennas and multiple receive antennas inherently provide a variety of channel links between a transmitter and a receiver in which the received signal at each transmit antenna is a superposition of the transmission signals from all transmit antennas. In typical wireless communication environments, due to signal scattering and reflection, the wireless channels between transmit antennas and receive antennas exhibit random fading with dynamic channel amplitude variation which is often characterized by Rayleigh distribution. The basic idea of coding and modulation for MIMO systems is to encode and map information bits into transmission signals across all transmit antennas. As long as one channel link is strong enough, there is possible to recover the information bits at the receiver side, and the chance that all channel links are weak is relatively low compared to the conventional SISO scenario.

The performance criteria of space-time coding and modulation were thoroughly developed by Guey et al. (1999) and Tarokh et al. (1998). In order to minimize the error probability of the MIMO signal transmission and decoding, space-time codes should be designed following two criteria as follows:

- *Diversity Criterion:* For any two distinct ST code words C and $\tilde{C}$, the rank of the difference matrix $C - \tilde{C}$ should be as large as possible. If the difference matrix between any two distinct code words is of full rank, we say the ST code achieves the full diversity.
- *Coding Gain Criterion:* The minimum value of the product $\prod_{i=1}^{\gamma} \lambda_i$ over all distinct ST code words C and $\tilde{C}$ should be as large as possible, in which λ_i are the non-zero eigenvalues of the difference matrix between two different

code words C and $\tilde{C}$. This quantity is related to the coding gain of the ST code.

The diversity criterion is more important of the two since it determines the slope of the error performance curve. In order to achieve the maximum diversity, the difference matrix $C - \tilde{C}$ has to be full rank for any pair of distinct ST code words C and $\tilde{C}$. The coding gain criterion is of secondary important which should be optimized if the full diversity is achieved. Based on the two code design criteria, a large number of ST signal/code designs have been proposed (see, e.g., Alamouti 1998; Tarokh et al. 1999; Ganesan and Stoica 2001; Tirkkonen and Hottinen 2002; Su and Xia 2002, 2003; Su et al. 2004; Jafarkhani 2001; Sharma and Papadias 2003; Su and Xia 2004; Hochwald and Sweldens 2000; Hughes 2000; Hochwald and Marzetta 2000; Hochwald et al. 2000; Shokrollahi et al. 2001; Hassibi and Hochwald 2002; Damen et al. 2002; Damen and Beaulieu 2003; Xin et al. 2003; Belfiore et al. 2005; Oggier et al. 2006 and the references therein).

An important code design approach is to construct space-time block codes (STBC) from orthogonal designs which have been widely used in practical wireless communication systems including WiFi local area networks and wireless cellular networks. Orthogonal STBC can guarantee to achieve full diversity performance and have simple fast maximum-likelihood (ML) decoding. In 1998, Alamouti proposed the first orthogonal STBC (Alamouti 1998) for MIMO systems with two transmit antennas:

$$G_2(x_1, x_2) = \begin{bmatrix} x_1 & x_2 \\ -x_2^* & x_1^* \end{bmatrix}, \quad (1)$$

in which x_1 and x_2 can be arbitrary complex information symbols with power constraint $E||G_2||_F^2 = 4$. The proposed scheme has an interesting property that for arbitrary complex symbols x_1 and x_2 , the columns of G_2 are orthogonal to each other. Later, Tarokh et al. extended the concept and proposed a series of orthogonal STBC for MIMO systems with

any number of transmit antennas (Tarokh et al. 1999; Ganesan and Stoica 2001; Tirkkonen and Hottinen 2002; Su and Xia 2003; Su et al. 2004). For example, for MIMO systems with $M_t = 3$ or 4 transmit antennas, orthogonal STBC with code rate $R = 3/4$ (i.e., the number of embedded information symbols per time slot) was presented in Tarokh et al. (1999), Ganesan and Stoica (2001), Tirkkonen and Hottinen (2002), and for $M_t = 2^k$ ($k = 1, 2, 3, \dots$); a recursive expression for orthogonal STBC was given in Su and Xia (2003). In general, the orthogonal STBC code designs are related to the theory of orthogonal designs which has a long history in mathematics (Geramita and Seberry 1979). The orthogonality of the resulting STBC code structure ensures that the codes achieve the full diversity order and have the fast ML decoding algorithms.

Note that the code rate of the orthogonal STBC decreases in terms of the number of transmit antennas as $(n_0 + 1)/(2n_0)$ if the number of transmit antennas is $n = 2n_0$ or $n = 2n_0 - 1$ (Su et al. 2004). Due to the code rate limitation of the orthogonal STBC, quasi-orthogonal STBC was proposed in Jafarkhani (2001) to relax the orthogonality requirement in exchange of the rate increase. In the quasi-orthogonal STBC designs, the columns of the code matrix are grouped such that the columns within a group may not be orthogonal, while the columns belonging to different groups are orthogonal to each other. Later, Sharma and Papadias (2003), Su and Xia (2002, 2004), the concept was further extended to design full-diversity quasi-orthogonal STBC in which some of the information symbols are chosen from a rotated version of the conventional symbol constellation with a specifically designed rotation angle. With the moderate decoding complexity increase, the resulting full-diversity quasi-orthogonal STBC can achieve both full code rate and full diversity performance.

A simple yet effective coding scheme to achieve the full space-time diversity is the cyclic STBC which was proposed around 2000 (Hochwald and Sweldens 2000; Hughes 2000):

$$C_l = \sqrt{M_t} \text{diag}\{e^{ju_1\theta_l}, e^{ju_2\theta_l}, \dots, e^{ju_{M_t}\theta_l}\}, \quad (2)$$

where $l = 0, 1, \dots, L - 1$, $\theta_l = \frac{l}{L}2\pi$ and $u_1, u_2, \dots, u_{M_t} \in \{0, 1, \dots, L - 1\}$ are some integers selected to achieve the full diversity and maximize the coding gain. The cyclic STBC has a simple diagonal code structure, and it is a special case of unitary STBC codes. A variety of more general unitary STBC were proposed in literature that can guarantee to achieve the full diversity and have larger coding gain (see, e.g., Hochwald and Marzetta 2000, Hochwald et al. 2000, Shokrollahi et al. 2001, Hassibi and Hochwald 2002 and the reference therein). While the primary application of the unitary STBC is for MIMO differential modulation/demodulation, the resulting codes can also achieve the full diversity and the coding gain of some unitary codes even higher than that of orthogonal STBC. Also, the code structures of the unitary STBC and the design approach were later extended to design more general non-unitary STBC.

Non-unitary STBC code designs have more flexibility in constructing code structures to achieve full diversity and maximize coding gain. An interesting approach is to design algebraic STBC by applying some transforms such as Vandermonde transforms and Hadamard transforms over information symbols to form STBC codes (see, e.g., Damen et al. 2002, Damen and Beaulieu 2003, Xin et al. 2003 and the reference therein). The full diversity of the algebraic STBC is guaranteed based on the algebraic number theory. An enlightening example is the Golden code which was designed based on the Golden number $(1 + \sqrt{5})/2$ for MIMO systems with two transmit antennas (Belfiore et al. 2005). The Golden code achieves the full diversity and has full rate. The concept was also extended to design perfect STBC based on special number fields for MIMO systems with higher number of transmit antennas (Oggier et al. 2006).

Note that most STBC codes were designed for MIMO systems with frequency-nonselective (flat) fading environments. For MIMO broadband wireless communications, the channel may exhibit frequency selective fading, and one may consider space-frequency coding or space-time-frequency coding to exploit the available spa-

tial, temporal, and frequency diversity. Naturally many existing STBC may be applied for broadband MIMO systems; however, the codes have to be modified in certain ways in order to achieve all the full spatial, temporal, and frequency diversity (see, e.g., Bölcskei and Paulraj 2000, Blum et al. 2001, Su et al. 2003, 2005, Liu et al. 2002, Su et al. 2005 and the reference therein).

Key Applications

STBC has been used in various MIMO wireless communication systems including WiFi local area networks, 4G wireless cellular networks, and the emerging 5G wireless networks.

Sparse spreading multiple access

Definition

Sparse code multiple access (SCMA) is a nonorthogonal multiple access technique based on codebooks of sparse structure.

Historical Background

Future 5G wireless networks are expected to support massive connectivity, higher throughput, lower latency, and lower controlling signal overhead. Compared with the conventional orthogonal multiple access techniques such as *code division multiple access (CDMA)* and *orthogonal frequency division multiple access (OFDMA)* utilized in current networks, *nonorthogonal multiple access (NOMA)*, which has the advantage of higher resource utilization, is more promising in 5G network.

Motivated by the design of CDMA chip sequences, the idea of sparse spreading, called *Low Density Signature (LDS)*, was first proposed by Reza Hoshyar (Hoshyar et al. 2008). LDS is a special case of multicarrier CDMA with a few nonzero elements in a long spreading signature. This sparsity characteristic can reduce the complexity of the multiuser detection called *Message Passing Algorithm (MPA)* (Razavi et al. 2011, 2012). In an LDS combined with Orthogonal Frequency Division Multiplexing (OFDM) system, which is called LDS-OFDM

(Hoshyar et al. 2010), the capacity is proved to have a superior performance than OFDMA.

To meet the requirements of 5G, *Sparse Code Multiple Access (SCMA)* (Nikopour and Baligh 2013), a new nonorthogonal codebook-based multiple access method, is proposed by Huawei in 2013. SCMA can be seen as a generalization of LDS. In LDS, incoming bits are mapped to a QAM symbol, and the repetitions of the QAM symbol are transmitted through the subcarriers according to the designed signature. But in SCMA, incoming bits are directly mapped to multidimensional complex codewords selected from predefined codebook (Taherzadeh et al. 2014). Instead of simple repetition of QAM symbol in LDS, SCMA provides significant shaping gain with the multidimensional constellation design (Boutros et al. 1996). Similar to LDS, only a small number of dimensions are used to transmit data; therefore, the codewords of SCMA are sparse. In the SCMA codebook, the nonzero dimensions are corresponding to the subcarriers in use. Besides, SCMA can also utilize iterative MPA detection with near optimal performance in the MAP sense.

The current research studies of SCMA are mainly focused on *capacity analysis*, *codebook design*, *low-complexity decoding*, *resource allocation*, *blind detection*, and so on. In *capacity analysis* area, researchers compare the capacity of SCMA system with the LDS system (Cheng et al. 2015) and analyze the capacity of downlink massive MIMO MU-SCMA system (Liu et al. 2015). In *codebook design* area, the method of *Shuffling* (Taherzadeh et al. 2014) and the method based on star-QAM (Yu et al. 2015) are proposed to decrease the *Bit Error Rate (BER)*. In *low-complexity decoding* area, some algorithms like PM (Mu et al. 2015), Quasi-ML (Zou et al. 2016), List Sphere Decoding (Wei and Chen 2017) are proposed to reduce the decoding complexity. In *resource allocation* area, the SCMA downlink power allocation to maximize weighted sum-rate has been studied in Nikopour et al. (2014) and uplink resource allocation based on a special structure codebook studied in Li et al. (2016). In *blind detection* area, contention-based blind

detection is proposed to support Grant-free transmission (Bayesteh et al. 2014; Au et al. 2014).

Foundations

SCMA system mainly consists of two parts: SCMA encoder and SCMA decoder.

SCMA encoder can be defined as a mapping from $\log_2(M)$ bits to a K -dimensional codeword of size M selected from a predefined codebook. K dimensions are corresponding to K different orthogonal tones, such as OFDMA subcarriers. The K -dimensional codeword is a vector with only $N < K$ nonzero entries. Users cannot transmit data through the subcarriers represented by the other $N - K$ zero entries. Theoretically, each user can be allocated to more than one codebook, and each codebook can be utilized by more than one user generally.

Figure 1 shows an example of an SCMA encoder, with six layered codebooks (*variable nodes*) and four subcarriers (*function nodes*). Each row denotes a dimension, and each column means a 4-dimensional codeword. In each codebook, the constellation size is 4, which means there are four different codewords can be chosen. The white entries denote the zero elements and the colored entries denote the nonzero elements in the codebooks. For example, in Codebook 1, the entries in the first row is colored and the entries in the third row is white, which means the first dimension is nonzero and third dimension is zero. In each codebook, there are two nonzero dimensions with colored lattice. In an AWGN channel, the signal received in the base station is the superposition of the codewords selected from the codebooks.

Codebook design is the most important part in SCMA encoder. The target is to design a multidimensional lattice constellation with dimensional dependency and power variation of the constellation while maintaining large minimum Euclidean distance. Generally, there are three stages to design SCMA code (Nikopour and Baligh 2013; Taherzadeh et al. 2014): (1) *Mapping Matrix* determines the number of layers interfering at each subcarrier, which represents

the complexity of MPA detection. For example, Fig. 1 can be considered as a *mapping matrix*, which means that each layer will be interfered by two other layers. (2) *Constellation Points and Multidimensional Mother Constellation* design. First, design a base constellation with a maximized minimum Euclidean distance. Second, a unitary rotation, which might be designed to maximize the minimum product distance of the constellation, can be applied on the base constellation to control the dimensional dependency and power variation. Third, build the complex constellation using the rotated base constellation by shuffling. Last, utilize the rotation to minimize the projection points. (3) *Constellation Function Operator*, which includes several operators like *complex conjugate*, *phase rotation*, and *dimensional permutation*, aims to design distinct codebooks for the collision layers.

Currently, SCMA decoder usually utilizes MPA detection or improved version of MPA detection. There are three steps of the conventional MPA detection: (1) *Initialize the conditional probability*. For the SCMA system in Fig. 1, in each resource node, there are three layers collided and each layer has four possibilities of constellation points. Then there are $4 * 4 * 4$ combinations of transmitted signals which determine the number of conditional probabilities. (2) *Iterative message passing through the variable nodes and function nodes*. Function node passes the updated message to its neighboring variable nodes, then the variable node passes the updated message to its neighboring function node, which constitutes an iteration. (3) *Log-Likelihood-Rate(LLR) calculation*. After several iterations, LLR output can be calculated by the probability guess of codeword at each layer.

Key Applications

Sparse code multiple access technique will be utilized in future 5G networks, which will be applied mainly in three scenarios: (1) *Enhanced mobile broadband (eMBB)*, for example, Ultra HD video transmission

Sparse Code Multiple Access, Fig. 1 SCMA encoder

and High Speed Mobile Broadband Wireless Communication. (2) *Ultra-reliable and low latency communications (uRLLC)*, for example, unmanned and automatic driving. (3) *massive machine type of communication (mMTC)*, for example, Internet of things (IoT).

Definitions

Spatial modulation is a single-radio-frequency (RF) multiple-antenna-assisted information transmission technique that combines two types of modulation schemes: the classic amplitude and phase shift keying (APSK), and antenna index modulation. More specifically, at a transmitter, one of multiple transmit antenna elements is selected depending on a subset of the input bits, and then an APSK symbol modulated based on the remaining input bits is transmitted from the single selected transmit antenna element. Hence, both the indices of the activated antenna element as well as the APSK-modulated symbol convey information to the receiver. Since only a single antenna element is activated during each symbol interval, spatial modulation allows us to maintain a cost/energy-efficient single-RF transmitter structure despite the use of multiple transmit antenna elements.

Sparse Signal Processing

► [Big Data in 5G](#)

Sparse Spreading Multiple Access

► [Sparse Code Multiple Access](#)

Historical Background

Spatial modulation is one of the multiple-input multiple-output (MIMO) transmission techniques (Di Renzo et al. 2011, 2014, 2016; Sugiura et al. 2012; Yang et al. 2016), whereby multiple antennas are equipped at a transmitter and/or a receiver, used to enhance the achievable performance. Depending on the target gain attainable by multiple antennas, the

classic MIMO schemes are classified into four categories, namely, spatial multiplexing, spatial diversity, beamforming, and space division multiple access (SDMA), which allow us to achieve a rate enhancement, an increased reliability, a high signal-to-noise ratio, and a large number of supported users, respectively (Hanzo et al. 2009; Sugiura et al. 2012). In contrast with these four classic MIMO arrangements, spatial modulation has been recently recognized as a fifth MIMO concept because it achieves exclusive benefits and provides further design degrees of freedom, owing to its specific sparse use of transmit antenna elements.

In 2001 (Chau and Yu 2001), the original concept of spatial modulation was proposed, whereby the combination of activated transmit antenna elements per symbol interval conveys information bits. However, multiple RF chains are needed in this original arrangement of spatial modulation, and hence no benefits were attainable over the conventional MIMO techniques. However, in Haas et al. (2002), the modulation principle of Chau and Yu (2001) was modified to one relying on the activation of only a single transmit antenna element in each symbol interval, which enables a single-RF transmitter structure. This has become the basic principle of spatial modulation.

Since then, diverse spatial modulation related techniques have been proposed. For example, spatial modulation was combined with the other four MIMOs in order to simultaneously amalgamate multiple of the five MIMOs' functions. In Jeganathan et al. (2008), spatial multiplexing and spatial modulation were combined for the sake of attaining a high transmission rate while maintaining a reduced number of RF chains. In Sugiura et al. (2010) and Di Renzo and Haas (2013), spatial diversity and spatial modulation were used together for the sake of attaining both reliability and rate enhancement through a single RF transmitter. Additionally, the issues of channel estimation (Sugiura and Hanzo 2012), non-orthogonal multiple access (Wang et al. 2017), differential modulation (Bian et al. 2013), reconfigurable-antenna-based modulation (Sugiura 2014; Boudida et al. 2016), and cooperative

communications (Sugiura et al. 2011a) have been investigated in the context of spatial modulation.

Foundations

Transmitter Model

Figure 1a portrays the transmitter model of spatial modulation. We assume M transmit antenna elements are equipped and L -size APSK constellations. At the spatial modulation transmitter, a single APSK-modulated symbol is transmitted during each symbol interval while typically assuming the use of a single-carrier transmission. Note that in order to maintain a single-RF transmitter structure, the symbol duration has to be less than the symbol interval (Sugiura et al. 2017). Importantly, spatial modulation is characterized by the sparse use of transmit antenna elements, while the four classic full-RF MIMO schemes rely on the simultaneous use of all/multiple transmit antenna elements, as shown in Fig. 1b.

More specifically, in each symbol interval, $B = \log_2 M + \log_2 L$ information bits are input to the spatial modulation encoder. Here, one of M indexed transmit antenna elements is selected based on the $\log_2 M$ input bits, and the $\log_2 L$ input bits are modulated onto an APSK symbol. Finally, the APSK-modulated symbol is transmitted from the activated transmit antenna element. Hence, the normalized transmission rate of spatial modulation is formulated by

$$B = \log_2 M + \log_2 L \quad [\text{bits/symbol}], \quad (1)$$

which increases logarithmically with an increase in the number of transmit antenna elements. The transmission rate (1) of spatial modulation is typically lower than that of spatial multiplexing, i.e., $M \log_2 L$ bits/symbol, when considering the same number of transmit antenna elements. This is because the transmission rate of full-RF spatial multiplexing increases linearly with the number of transmit antenna elements.

Since only a single transmit antenna is used in each symbol interval, the spatial modulation

Spatial Modulation, Fig. 1 Transmitter structures: (a) single-RF spatial modulation and (b) full-RF spatial multiplexing. © 2017 IEEE. (Reprinted, with permission, from Sugiura et al. 2017)

transmitter needs only a single RF chain, which is a specific benefit of spatial modulation. Note that, as shown in Fig. 1b, a classic MIMO transmitter typically imposes the requirement of a full-RF structure, where the number of RF chains is the same as that of transmit antenna elements. As mentioned in Di Renzo et al. (2014), the dynamic RF power consumption, the static power consumption imposed by the circuit (e.g., the power amplifier), increases linearly with the number of transmit antenna elements in a conventional full-RF MIMO transmitter. Naturally, the transmitter cost can easily be made low for a low number of RF chains. Hence, spatial modulation is espe-

cially beneficial for the massive MIMO scenario, where a substantially large number of transmit antenna elements are used.

Receiver Model

Consider the receiver to be equipped with N receive antenna elements. By assuming a single-carrier transmission over a frequency-flat fading channel for the sake of simplicity, the received signal model of the spatial modulation system is represented by

$$\mathbf{y} = \mathbf{H}\mathbf{s} + \mathbf{n}, \quad (2)$$

where $\mathbf{y} \in \mathcal{C}^N$ are the received signals, and $\mathbf{H} \in \mathcal{C}^{N \times M}$ are the MIMO channel coefficients. Furthermore, $\mathbf{s} \in \mathcal{C}^M$ is the transmit symbol vector, where there is only a single non-zero element, corresponding to an activated transmit antenna element. Also, $\mathbf{n} \in \mathcal{C}^N$ comprises the associated additive white Gaussian noise (AWGN) components, which are represented by random variables obeying the zero-mean complex-valued Gaussian distribution having variance of N_0 .

Note that, while in spatial multiplexing the effects of inter-channel interference (ICI) are imposed at the receiver, the spatial modulation receiver does not suffer from the effects of ICI, as an explicit benefit of the spatial modulation scheme's principle of a single transmit antenna activation. This allows us to benefit from low-complexity detection algorithms (Sugiura et al. 2011b), which are suitable for operation in mobile handsets.

While in most of the detection algorithms developed for spatial modulation frequency-flat fading scenarios were assumed, some practical equalizers of spatial modulation were proposed for frequency-selective fading scenarios (Rajashekar et al. 2013; Sugiura and Hanzo 2015).

Fundamental Limitations

Against the above-mentioned benefits specific to spatial modulation, there are some fundamental limitations imposed (Sugiura et al. 2017), which remain open issues.

- *Pulse shaping:* A spatial modulation transmitter typically has to transmit a whole symbol during a symbol duration, due to the symbol-wise antenna switching principle, as shown in Fig. 1a. Hence, time-orthogonal bandwidth-efficient shaping filters, such as root raised cosine filters, are not available under spatial modulation. However, most of the previous studies on spatial modulation do not take into account this limitation. As an exceptional example, in order to reduce the effects of this information-theoretic penalty imposed by time-limited pulse shaping, the use of two RF

chains, rather than a single one, was proposed in Ishibashi and Sugiura (2014).

- *Single-carrier transmission:* Spatial modulation does not have any compelling gain over the conventional single-antenna-based system when used with orthogonal frequency-division multiplexing (OFDM) (Sugiura and Hanzo 2015). This is because, in a single-RF spatial modulation transmitter, subcarrier-wise antenna selections are not practical, and hence only frame-wise antenna selection is possible. However, OFDM typically employs at least hundreds of subcarriers, and the rate enhancement attained by spatial modulation becomes negligible in such a scenario. For this reason, spatial modulation clearly has to employ single-carrier transmissions rather than multi-carrier ones. Furthermore, since the current wireless standards assume broadband communications, single-carrier transmissions typically suffer from frequency-selective channels, experiencing a long-tap delay, hence requiring the use of efficient equalizers, such as those of Rajashekar et al. (2013), Sugiura and Hanzo (2015), at the receiver.

Key Applications

As mentioned above, spatial modulation is characterized by a high energy efficiency and a low cost, owing to a single-RF MIMO transmitter structure, as well as an ICI-free low-complexity receiver structure. Therefore, key applications of spatial modulation are expected in both uplink and downlink scenarios in cellular systems, as follows:

- *Downlink scenario (Sugiura et al. 2017):* Since a base station has the capability of having a large-scale antenna array installed in a next-generation of wireless systems, spatial modulation is beneficial for high-rate spatial-modulation-based symbol transmission. Furthermore in general, spatial modulation operates in an open-loop manner, whereby a transmitter does not need any feedback associated with channel state information from the receiver. Hence, frequency-division

duplex as well as time-division duplex can be used for massive-MIMO spatial-modulation downlink, unlike a massive MIMO system based on spatial multiplexing (Larsson et al. 2014). More importantly, in the massive MIMO based on spatial modulation, the static energy consumed by an RF circuit is kept low, owing to the single-RF transmitter structure. Furthermore, since signals received at a receiver are free from ICI, a low-complexity detection algorithm suitable for a mobile handset becomes possible.

- *Uplink scenario* (Wang et al. 2015): Spatial modulation is also beneficial for an uplink scenario where multiple mobile terminals communicate with a base station equipped with a large number of antenna elements. Since each mobile terminal needs only a single RF chain in spatial modulation, despite the use of multiple transmit antennas, spatial modulation is useful for maintaining a simplified mobile handset architecture, unlike the conventional full-RF MIMO one.

Moreover, when considering the use of high carrier frequencies, such as in the millimeter wave case, the antenna size and separation both become significantly small, and hence the installation of a large-scale antenna array becomes realistic. This is especially beneficial for spatial modulation, since an exponential increase in the number of transmit antenna elements is needed for a linear increase in the transmission rate.

Furthermore, the use of spatial modulation in visible light communications has been also considered (Fath and Haas 2013). This is for the sake of increasing the spectral efficiency, because in general, the modulation bandwidth of light-emitting diodes is limited.

[Cognitive radio](#); [Spectrum access](#); [Spectrum resource allocation](#)

Definition

In recent years, the spectrum allocation mode based on static authorization has been unable to ever-increasing spectrum demand. There are a lot of unused spectrum resources in both the time domain and frequency domain on a dedicated frequency band. However, some frequency bands are too crowded, such as the mobile phone communication band. It results in the uneven distribution and waste of the spectrum resources (Cabric et al. 2004). The key idea of cognitive radio is to perceive the environment using devices that have communication sensing capabilities. It can perceive and respond to the current communication

environment such as spectrum bandwidth, idle time slot, main user mode, and so on. Moreover, it can make full use of the available spectrum resources to solve the problem of low frequency utilization rate under the traditional distribution mode.

Historical Background

The term cognitive radio was first proposed by Joseph Mitola based on the concept of software radio. In 1999, Mitola described a cognitive radio system in his doctoral thesis, which enhanced the flexibility of personal wireless services through a wireless knowledge description language, extended the cognitive radio, and gave an interesting conceptual summary of the interdisciplinary cognitive radio. He believes that software radio is the ideal platform for implementing cognitive radio (Mitola 2001). In his dissertation, Joseph Mitola had studied the learning and reasoning capabilities of realizing cognitive radio through software at high-level, but there was still a lack of research on the physical layer and link layer of the special wireless architecture. In 2001, Simon Haykin further elaborated cognitive radio from the perspective of signal processing in an invitation. He thought that by changing the operating parameters (such as transmission power, carrier frequency, and modulation technology) of cognitive radio in real time to adapt to the statistical changes of the received radio signals, the two most important goals of cognitive radio: highly reliable communications at any time and any place and efficient utilization of spectrum resources can be achieved. In 2003, the FCC held a cognitive radio seminar to discuss the related technical issues of using cognitive radio technology to achieve flexible spectrum utilization. The FCC calls any radio system with adaptive spectrum sensing capability as cognitive radio and further describes cognitive radio applications and key technologies. At the same time as the theoretical research and development of cognitive radio technology, some scientific research projects related to it have also been

carried out in the world. Some representative examples are:

1. The cognitive radio spectrum pool system proposed by Prof. F. K. Jondral, Karlsruhe University, Germany, etc., is an OFDM-based centralized control dynamic spectrum access system. The system architecture includes base stations and mobile users. The research scenarios are mainly focused on the dynamic sharing of spectrum resources between OFDM wireless LANs (such as IEEE 802.11a/g) and GSM networks. With OFDM, specific sub-carriers can be zeroed, so that interference characteristics can be avoided and the available spectrum resources can be used dynamically. The spectrum pool system implements the perception of network available spectrum resources through a specially designed frame structure.
2. The European DRIVE/Over DRIVE project enables cognitive radio dynamic spectrum sharing among heterogeneous networks by establishing a common coordination channel. At present, the project studies two dynamic spectrum allocation algorithms: dynamic spectrum allocation in time and space domain. Time dynamic spectrum allocation refers to that a radio access network can use spectrum resources not currently used by other radio access networks in specific time; and spatial dynamic spectrum allocation allows spectrum allocation for adapting to service changes in different areas.
3. The American CORVUS system utilizes cognitive radio methods to use virtual unlicensed spectrum. The system was proposed by Professor R. W. Brodersen from the University of California, Berkeley, with the goal of detecting and utilizing spectrum in a coordinated manner. In the CORVUS system, the concept of user grouping is proposed. The utilization of dynamic spectrum in group users can be coordinated by the group control channel. And then, the dynamic spectrum distribution between groups can be coordinated by the common control channel. Finally, the reliable link maintenance protocol under dynamic

spectrum access was proposed. The system is developing test beds to evaluate the performance of physical and media access control layers.

4. The DIMSUM Net system is a network architecture proposed by researchers at Lucent Bell Labs and Stevens Institute of Technology for implementing Spectrum Statistical Multiple Access (SMA) through the Coordinated Access Band (CAB). The system uses the coordinated access frequency band to improve the spectrum access efficiency and fairness, and improves the spectrum utilization through statistical multiple access.

Foundations

In cognitive radios, the MAC layer is responsible for handling spectrum management units, which include spectrum sensing, decision making, sharing, and handover. This section provides an overview of spectrum sharing and allocation methods according to different classification criteria.

1. Classification methods: static allocation, dynamic allocation, and hybrid allocation (Hossain et al. 2009). Static allocation means that the frequency band is allocated to designated users according to authorization, and other unlicensed users cannot use the allocated spectrum resources. This allocation method leads to low spectrum utilization. The advantage is that there is no communication interference between users and the communication of authorized users can be fully guaranteed quality. In the dynamic allocation mode, the system allocates spectrum resources adaptively according to user requirements, which can increase the system efficiency. The disadvantage is that the calculation overhead is large and the system delay is caused. Hybrid spectrum allocation integrates static and dynamic resource allocation methods to ensure that the system benefits are increased when the amount of calculation is low.
2. Classification by frequency band type: It is divided into two types: open spectrum sharing and licensed frequency spectrum sharing. Open spectrum sharing refers to accessing unlicensed bands with undifferentiated access to various communication users, such as the 2.4 GHz spectrum for industrial medical and scientific research. Authorized frequency band sharing means that for frequency bands already allocated to authorized users, secondary users can reasonably use spectrum resources without disturbing the normal communication of the primary user. In this way, the primary user's communication quality is prioritized, and secondary users need to dynamically exit or occupy the frequency band in response to changes in the environment.
3. Classification by access technology: It can be divided into Underlay mode and Overlay mode. The noise detected by the cognitive user as the primary user in the underlay mode exists, and the access to the frequency spectrum of the authorized user is controlled by controlling the cognitive user's transmit power and spread spectrum on the premise of guaranteeing the authorized user communication quality. This mode usually corresponds to the allocation. The interference temperature model in the algorithm. Overlay mode, cognitive users need to constantly detect the network environment, only the primary user does not occupy the frequency band, secondary users can access the opportunity, the primary user must also promptly perform spectrum switching.
4. Classification by collaboration: cooperative spectrum allocation and noncooperative spectrum allocation. In the cooperative allocation mode, cognitive users accessing a frequency band need to consider the influence and needs of other cognitive users, and maximize the overall benefit as a criterion for spectrum allocation. In a noncooperatively distributed model, each cognitive user of the frequency spectrum to be allocated can be considered "selfish" and allocate resources with the goal of maximizing self-

efficacy. This model reduces many users compared to a collaborative approach. The amount of information exchanged between the calculations.

5. Classification by network structure: According to whether or not the decision center is divided into centralized and distributed spectrum allocation. In the centralized network structure, each cognitive user with sensing function needs to send the detection result to the decision center. The center allocates the spectrum to achieve maximum system efficiency. The disadvantage is that the central computing has large overhead and the algorithm is complex. In the distributed distribution mode, each user transmits the information of the perception result. The distribution result is related to the criteria adopted by cognitive users. This entry studies the distributed spectrum allocation algorithm.

Key Applications

The spectrum allocation of cognitive radio has many common features with the spectrum allocation of other communication systems. However, due to the characteristics of cognitive radios borrowing the spectrum of authorized users by themselves, the spectrum allocation must meet certain special requirements. The distribution principle is as follows:

1. Guaranteeing flexibility: Cognitive radios are radios that can detect available spectrum resources and choose to borrow the authorized user spectrum to communicate. Therefore, the information of the available spectrum must be updated in real time, and once the authorized user resumes the use of a certain spectrum space, the cognitive user must exit the frequency band within a short time and select other frequency bands for communication (Liang 2008). In this way, the most important feature of spectrum allocation technology in cognitive radios that is different from other wireless communication spectrum
- allocations is to ensure flexibility. Any spectrum allocation technology for cognitive radios must have strong spectrum backoff and conversion capabilities, and due to the constant update of available spectrum information, the corresponding spectrum allocation algorithm must also meet the requirements of real-time performance.
2. Improving system performance: The primary purpose of spectrum allocation technology is to allocate the available spectrum space reasonably so that the system performance is improved or approached to an optimal state. Depending on the needs of different applications, the performance requirements of a certain cognitive system may also be different. For example, the goal is to minimize system interference, to increase the fairness of spectrum allocation, to maximize system throughput, and so on. According to different system application requirements, different algorithm objective functions are proposed to guide the design of the spectrum allocation algorithm.
3. Reducing signaling overhead and computational complexity: The design of the spectrum allocation algorithm will undoubtedly require a certain amount of algorithm signaling to transmit and occupy a certain amount of computing time. These can be seen as the overhead incurred by the allocation algorithm. Of course, it is hoped that the spectrum allocation function can be realized with relatively little overhead. Therefore, the spectrum allocation algorithm must be designed to take into account the complexity of control signaling between users and between the user and the central controller, distributed on the user or the central controller. The amount of algorithm calculation is also a problem that needs to be considered.

In short, the spectrum allocation of cognitive radio has a certain degree of universality and particularity and must be fully considered when designing spectrum allocation algorithms to meet the design principles listed above.

Future Directions

Game Theoretic Model: The cognitive radio spectrum allocation process can be abstracted as a game theoretic model. The cognitive user of each channel to be allocated in cognitive wireless network is a participant. The element in the behavior set of decision making is that the cognitive user selects the access channel from the list of available spectrum, and the benefit of network system after the allocation is finished. For example, spectrum efficiency is the utility of game process.

Interference Temperature Model: The interference temperature is similar to the noise temperature and is a comprehensive consideration of the interference generated by the user and its frequency band width. Cognitive users need to adjust the transmitting power or spectrum of the transmitter to not exceed the interference temperature of the main user by detecting the interference of the authorized user, and the power control plays a decisive role in the temperature interference model (Urkowitz 1967). According to the different interpretations of the signal and noise, it can be divided into the rational interference model and the generalized interference model.

Graph Theory Model: Spectrum allocation mathematical model is based on the corresponding interference and constraints. In the study of spectrum allocation in cognitive radio systems, the network topology of cognitive users is abstracted into a graph. Each vertex in the graph represents a wireless user and each edge represents a collision or interference between a pair of vertices.

Auction Bidding Model: Auction model requires an auctioneer to be responsible for allocating spectrum resources, so the model corresponds to the centralized spectrum allocation algorithm mentioned above, where each cognitive user, as a bidder, makes a price tag for the spectrum resources required. Unlike auction in the traditional economic sense, nodes cannot interfere with each other, such as neighbor users who are too close to each other cannot occupy the same frequency band.

Definitions

Cognitive radio is a wireless communication system with intelligence, which senses its outside electromagnetic environment and learns from the surroundings and then adapts its internal states by changing certain operating parameters such as transmission power, carrier frequency, and modulation strategy in order to adapt to the changes of its environment.

Spectrum hole is a band of frequencies assigned to a primary user/licensed user but is not being utilized at a particular time and specific geographic location.

Spectrum sensing is the process of periodically monitoring a specific frequency band with the aim to identify the presence or absence of primary users/licensed users.

Historical Background

The useable electromagnetic radio spectrum which is a precious natural resource has been exclusively allocated to different wireless services by regulatory bodies. However, there have been several studies and reports over the years show that a large portion of licensed spectrum is actually underutilized in both temporal and spatial domains. On the other hand, the spectrum resource demands for services in the fifth-generation (5G) wireless communications, internet of things (IoT), and ad hoc vehicular network (VANET) are increasing dramatically. Therefore, there is a contradiction between the underutilized spectrum and increasing demand.

In order to solve the aforementioned challenge, cognitive radio (CR), regarded as a key technology, emerges as a novel form of wireless communications to improve spectrum efficiency. The concept of CR was first proposed by Joseph Mitola in 1999, and he defined a CR as "A radio that employs model based reasoning to achieve a specified level of competence in radio-related domains (Mitola 1999)." Mitola introduced a new language called the radio knowledge representation language (RKRL) which could be used by CR to enhance the flexibility of personal wireless

services. The idea of RKRL was expanded further in Mitola's doctoral dissertation, and this work was presented at the Royal Institute of Technology, Sweden, in May 2000 (Mitola 2000). In November 2002, the Federal Communications Commission (FCC) published a report prepared by the Spectrum Policy Task Force, aimed at improving the spectrum resource management in the United States (Kolodzy and Avoidance 2002), and the report was presented at a workshop focusing on CR, which was held in Washington, DC, in May 2003. This workshop was followed by a conference on CR held in Las Vegas, NV, in March 2004.

CR is built on a software-defined radio, and it is an intelligent wireless communication system that is aware of its environment (Haykin 2005). CR can learn from the radio environment and adapt to statistical variations in the input radio frequency (RF) stimuli by adjusting the transmitting parameters, such as power output, frequency, and modulation to ensure an optimized communications experience for users. Through interaction with the environmental RF stimuli, CR forms a cognitive cycle, which is demonstrated in Fig. 1.

In a cognitive radio network (CRN), there are two types of users: primary users (PUs) and secondary users (SUs). PUs are also referred to as licensed users, and SUs are referred to as unlicensed users. SUs probe for spectrum access opportunities through spectrum sensing to prevent harmful interference on the ongoing transmissions of PUs. Spectrum sensing plays an important role in CR. The aim of spectrum sensing is to detect a spectrum hole precisely in order to share the spectrum without harmful interference to other users. In order to guarantee the SUs can access the spectrum hole reliably and to utilize the band effectively without interfering with the PUs, various spectrum sensing techniques have been discussed in literatures.

Foundations

There are many ways to classify spectrum sensing schemes, and the most popular one is categorized by noncooperative spectrum

Spectrum Sensing in Cognitive Radio Networks, Fig. 1
Cognitive cycle

sensing and cooperative sensing. Noncooperative spectrum sensing is referred to as transmitter detection which mainly includes energy detection, matched filter detection, waveform-based sensing, and cyclostationary feature detection, while cooperative sensing is termed as receiver detection.

In noncooperative spectrum sensing, SUs detect the presence or absence of PU's signal, which can be regarded as a binary hypothesis testing problem. The received signal at the SU receiver can be expressed as

$$y(n) = \begin{cases} w(n), & H_0 \\ x(n) + w(n), & H_1 \end{cases} \quad (1)$$

where $w(n)$ denotes the additive white Gaussian noise (AWGN). The signal that comes from a PU transceiver and is received at the SU receiver is denoted as $x(n)$. H_1 and H_0 represent the presence and absence of the primary signal, respectively.

Energy detection (Digham et al. 2007) performs well if the noise power at the receiver is prior knowledge. However, the performance of the energy detector can be significantly degraded due to uncertainty in the noise power, which gives

rise to its unreliable nature. Thus, many recent research works focus on overcoming the noise uncertainty problem, i.e., cooperatively senses the noise energy to reduce the uncertainty to its minimal level.

A matched filter is a linear filter designed to maximize the output signal-to-noise ratio (SNR) of a given input signal, and it is known to be an optimal coherent detector in nature. Prior knowledge of the modulation type and carrier frequency of the PU is required for the matched filter detectors. Therefore, when the SU has prior knowledge not only about the various parameters of the physical implementation but also the physical structure of the primary signal, matched filter detection is applied. Otherwise, the correlation becomes poor, and the detection accuracy is degraded because of the unknown knowledge such as fading channel coefficients or a possible frequency offset.

Waveform-based detection is applicable to a system with known signal pattern which includes preambles, midambles, pilot patterns, spreading sequence, etc. A preamble is a known sequence transmitted before each burst, while a midamble is delivered in the middle of a burst or slot. Such kind of spectrum sensing method is also referred to as coherent sensing. Waveform-based detec-

tion has higher reliability and converges faster than energy detection. The performance of the waveform-based detection approach increases as the length of the known signal pattern increases.

Cyclostationary feature detection (Sutton et al. 2008) captures the features of received signals and identifies the noise energy of the modulated signal energy from the aperiodic characteristics of the noise signal. In other words, cyclostationary feature detection method deals with the inherent cyclostationary properties that cannot be found in any interference signal or stationary noise. More specially, the detection approach utilizes cyclic correlation periodicity in the received primary signal to identify the presence of PUs. Therefore, the cyclostationary feature detection method is a reliable method of spectrum sensing at low SNR as it possesses higher noise immunity than any other spectrum sensing schemes. But, on the other hand, this detection method requires prior knowledge of the signal parameters of primary signal, such as chip rate, channel code, and symbol rate, which has high computational costs (Gardner 1990).

In reality, since the primary signal suffers from multipath fading, the signal received at the SU receiver may not be sensed correctly. In addition, more accurate spectrum sensing performance takes longer observation time which will cause the incorrect spectrum utilization. Moreover, the hidden terminal problem that the SU receiver is blocked by a building or a wall can lead to incorrect spectrum sensing. To this end, cooperative spectrum sensing is emerged to overcome the aforementioned drawbacks in which SUs perform spectrum sensing in a coordinated and cooperative manner. In cooperative spectrum sensing, each SU independently implements local spectrum sensing and then reports either a binary decision (hard decision) or a test statistic (soft decision) to a combining user or fusion center. Then, the combining user or fusion center makes a decision on the presence or absence of the primary signal based on its received information. Through cooperation, SUs can share their sensing information for making a combined decision more accurate than the individual decisions. Therefore, the probability of misdetection or false

alarm is decreased by using cooperative spectrum sensing. The aim of cooperative spectrum sensing is to improve the sensing performance by exploiting the spatial diversity from spatially located SUs (Akyildiz et al. 2011). The performance improvement due to spatial diversity is called cooperative gain. Based on the methods used by SUs to share their sensing information, cooperative sensing schemes can further be classified into centralized sensing and distributed sensing.

In centralized sensing, a central controller collects sensing information from the SUs who have the sensing capability. Based on the obtained information, the central controller identifies the available spectrum and then broadcasts the spectrum information to all the SUs who are desiring for spectrum access opportunities. More specially, the sensing results with local decisions, either hard or soft, are gathered at the central controller through a control channel which is for reducing the probability of misdetection. However, this kind of sensing mechanism consumes lots of bandwidth. For distributed sensing, SUs share information among each other, but they make their own decisions of which part of the spectrum they can use. Distributed sensing has more advantages than centralized sensing, i.e., there is no need for a backbone infrastructure which reduces the sensing cost.

In spectrum sensing, another important issue is interference temperature detection, which measures the interference level observed at an SU receiver and is used to protect PUs from harmful interference due to SUs' opportunistic spectrum access. Although interference is regulated by the transmitters, it actually occurs at the receivers. Interference-based detection is one important method in CRN since an SU is allowed only if it does not degrade the quality of service (QoS) of a PU, which means an SU transmits only while the interference caused by its own transmission is below a specific threshold which is also referred to as the interference temperature limit. Each PU has an interference temperature limit which can guarantee a certain QoS of the PU. The SU will measure the interference environment and adjust its transmission such that the interference to the PU is not above the interference limits.

Thus, interference-based detection is an underlay scheme based on an estimation of the interference level at the primary receiver. An interference-based detection is discussed in Lin et al. (2013). Using the interference temperature parameter, two crucial controls can be defined as follows: (1) channel is declared to be occupied when the interference temperature is above the upper-bound threshold; (2) channel is declared empty or available for SUs while the interference temperature is below the lower-bound threshold.

Key Applications

Spectrum sensing technology is fundamental in the scenarios where the users would like to access the licensed bandwidth, i.e., the vehicles are using TV bands for communications in the vehicular ad hoc network.

Spectrum Sensing with Power Recognition

Danyang Wang and Zan Li
Xidian University, Xi'an, China

Synonyms

[Signal detection](#); [Transmission power classification](#)

Definitions

Spectrum sensing with power recognition is the task of obtaining awareness about the existence of the primary user (PU) as well as the transmission power being used by the PU in a geographical area. The operators of spectrum sensing with power recognition are the secondary users (SUs) who have no licensed spectrum bands while seeking the opportunity to exploit the spectrum hole.

Historical Background

Spectrum sensing is the most important component to support the cognition cycle which has been first proposed by Joseph Mitola in 1999 (Mitola and Maguire 1999). The main function of spectrum sensing in this cognition cycle is to sense its surrounding environment (i.e., outside world). In 2005, a more concise cognition cycle was introduced by Simon Haykin, where the task of spectrum sensing was to detect the spectrum holes and measure the noise floor statistics

(Haykin 2005). Later on, IEEE Standards Association has made significant contributions in establishing the bridge between research results and widespread deployment of the spectrum sensing. More specifically, IEEE 1900.6 working group has started a standardization project on the topic of spectrum sensing in advanced radio systems. The baseline standard IEEE 1900.6 for spectrum sensing interfaces and data structures was released in 2011 (575 2011). Then the first amendment assigned as 1900.6a was released in 2014 (682 2014), and the latest amendment assigned as 1900.6b on the topic of the usage of spectrum sensing information to support spectrum databases was released in 2016 (741 2016). Moreover, IEEE 802.22 standard of wireless regional area networks (WRAN) in TV bands was released in 2011, where spectrum sensing was a key function of the cognitive plane (ieee 2012). With the release of IEEE 802.22 series, LTE, and LTE-A standards, the PU could operate under more than one discrete transmission power. Thus, spectrum sensing with power recognition that can detect the presence and transmission power of the PU has attracted more attention recently.

Foundations

With cognitive radio being used in a number of applications, the area of spectrum sensing with power recognition to effectively detect the presence and the transmission power of the PU has become increasingly important. The basic ability of spectrum sensing with power recognition is to keep monitoring the spectrum band to ensure that the SU cannot cause harmful interference to PUs. When performing spectrum sensing with power recognition, the SU may work with two kinds of operation types:

- **Periodic sensing:** When a single RF chain is utilized to process both the sensing and data transmission in the single radio architecture, only a specific time slot can be allocated for spectrum sensing and power recognition. In

this case, the spectrum efficiency is limited, since a part of the available time slot is used to perform spectrum sensing instead of data transmission (Zhang et al. 2014b).

- **Continuous monitoring:** The capability that continuously senses the spectrum occupancy and identifies the transmission power is very necessary for the SU in practical cognitive radio systems. The SU is allowed to exploit the available spectrum on a noninterference basis to the PU. When the PU returns to the spectrum, the SU needs to detect the PU's activity immediately by leveraging continuous monitoring (Zhang et al. 2014a). The continuous monitoring can be realized in the dual-radio architecture, where one radio chain is allocated to data transmission, while the other chain is dedicated to spectrum monitoring.

Technically, both periodic sensing and continuous monitoring rely on the SU which can be able to detect very weak signals transmitted by the PU and identify the transmission power of the PU. This sophisticated processing procedure is usually completed by excavating a specific feature of the PU's transmitted signal. On theoretical aspect, detecting the presence and identifying the transmission power of the PU can be described by the multiple hypotheses test problem. In this framework, the SU declares a specific hypothesis is true only if the measurement of signal features is located in the predetermined decision region. A number of features can be leveraged to calculate the measurement, which yields to various spectrum sensing with power recognition schemes.

Matched filter detector-based scheme is known as the optimal coherent detector under additive white Gaussian noise (AWGN) channels. In this scheme, the test statistics is calculated by employing cross-correlation between the known sequence and the received signal (Zhang et al. 2015). Then, the occupancy of the spectrum is detected by examining the test statistics with predetermined threshold. Moreover, the transmission power used by the PU is identified by utilizing minimum Bayes risk criterion. Although matched filter-based scheme can provide a superior performance, it requires the

SU to be aware of prior information about the PU. Practically, it is not always easy to obtain the prior information of the PU. In this case, the sensing and recognition performance of matched filter-based scheme degrades severely.

Energy detector-based scheme is the most common way of spectrum sensing with power recognition due to low computational complexity. Moreover, the energy detector-based scheme requires no prior knowledge of the PU's signal, which makes it more generic (Gao et al. 2015). In the energy detector-based scheme, the absolute square of the received signal is calculated and averaged over the sensing slot to obtain the test statistics. The activity status as well as the transmission power of the PU is detected by comparing the test statistics with predetermined decision thresholds. However, the energy detector-based scheme makes poor performance under low signal-to-noise ratio. In addition, the noise power is required to calculate decision thresholds, such that a lower estimation error on the noise power may result in a severe degradation on the sensing and recognition performance.

When the SU is equipped with multiple antennas, a promising spectrum sensing with power recognition scheme was proposed Li et al. (2016), where the maximum eigenvalue of the received sample covariance matrix is used to identify the status of PU. To calculate the decision regions, it is very necessary to derive the probability density function (PDF) of the maximum eigenvalue firstly. The exact PDF of the maximum eigenvalue can be derived by leveraging the random matrix theory. However, the exact PDF of the maximum eigenvalue is extremely complicated. Thus, it is hard to utilize the exact PDF to calculate the decision regions. In practice, non-asymptotic Gaussian approximation and gamma approximation are usually used to obtain the PDF of the maximum eigenvalue by fitting the first- and second-order moments of the maximum eigenvalue. Therefore, the closed-form expression of the decision regions as well as the closed-form performance analysis can be derived concisely. The eigenvalue-based spectrum sensing with power recognition scheme requires no prior

information of the PU's signal, which makes it a blind spectrum sensing scheme.

When the transmitted signals are non-Gaussian process, the high-order cumulant-based spectrum sensing with power recognition scheme can efficiently detect the presence of the PU and recognize the transmission power of the PU by leveraging the high-order statistical feature of the received signal (Wang et al. 2018). It is well known that cumulants higher than second order are zero for a Gaussian random process. Hence, the high-order cumulant-based spectrum sensing with power recognition scheme can eliminate the effect of Gaussian noise on the sensing and recognition performance. Additionally, to achieve more accurate sensing and recognition performance, hybrid multiple high-order cumulant-based spectrum sensing and power recognition has been proposed, where the rich statistical information of the received signal is excavated.

To illustrate the performance of spectrum sensing with power recognition scheme, three probabilities are commonly explored: probability of false alarm, probability of detection, and probability of recognition. Probability of false alarm is the probability of an incorrect decision, where the SU claims the monitored spectrum is occupied when the PU is actually inactive. Probability of detection is the probability of detecting a signal on the monitored spectrum band when the PU is truly active. Furthermore, probability of recognition describes the capability that the SU correctly identifies the transmission power being used by the PU. Generally, probability of false alarm should be kept as small as possible, in order to ensure the opportunity for reusing the idle spectrum, while the probability of detection and probability of recognition should be achieved as high as possible to prevent the PU from being harmfully interfered.

Key Applications

Spectrum sensing with power recognition can be used in LTE-U systems, where the cellular network shared unlicensed spectrum with Wi-

Fi system. Specifically, the spectrum sensing with power recognition is utilized to find available unlicensed spectrum band, which can be exploited by the cellular network to offer higher capacity without affecting the performance of Wi-Fi systems.

Definitions

Machine-learning (ML) techniques in LTE networks mean to apply machine-learning algorithms in LTE network to improve the network performance.

History Background

Learning is a kind of important intelligent behavior that human beings have. At present, computers have also acquired this ability initially, and this is machine learning (ML). A classic definition is machine learning is a field of computer science that gives computers the ability to learn without being explicitly programmed. In short, machine learning refers to the acquisition of new experiences and knowledge through the inherent regularity of computer learning data to improve the intelligence of computers and enable computers to make decisions like human beings.

ML is an important subject that gives machine intelligence and solves many problems. ML techniques can be applied to different areas of LTE. And history of machine learning can be traced back to the twentieth century.

- In 1943, Warren McCulloch and Walter Pitts proposed the neural network hierarchy model and established a computational model theory of neural network, which laid the foundation for the development of machine learning.
- In 1950, the “Father of Artificial Intelligence” Turing developed the famous “Turing Test,” making artificial intelligence an important research topic in the field of computer science.
- Till the summer of 1980, the first international symposium on machine learning, held at Carnegie Mellon University in the United States, marked the rise of machine learning in the world. In the 1980s, researches about neural network increase gradually, which includes backpropagation algorithm (BP) (Hopfield 1982), convolutional neural network (CNN), and so on. These are based on knowledge from samples.
- In the 1990s, many statistical learning models have attracted the researchers’ attention, such as support vector machine, kernel method, and so on. However, research on this field began from the 1960s. Vapnik proposed the concept of support vector in 1963 (Vapnik 1998). Since the 1990s, the superiority of statistical learning is shown in text classification application.
- In the 2000s, the problem of shallow learning is gradually exposed, because the limited sample and calculation unit led to limited expression ability of complex functions and data. The learning ability is not strong, which can only extract the primary characteristics. Thus, in 2006, Geoffrey Hinton published an article (Hinton and Salakhutdinov 2006), which proposed a deep learning model. The introduction of this model opens up a new era of deep neural network machine learning. Deep learning in recent years has made impressive progress in many fields and launched a number of successful commercial applications, such as Google Translate, Apple Siri voice tools, Microsoft Cortana, and especially the Google AlphaGo which uses Monte Carlo tree search algorithm and artificial neural networks to defeat the European Go champion Fan Hui (Fu 2016).

Since LTE launched in 2004, few years later, research on machine-learning techniques in LTE networks becomes hot topic. Till now, there are still many researchers focus on this field.

Foundations

Machine learning has becoming a useful tool to solve complex problems in many fields. Meanwhile, many functions and implementations in LTE network require the assistance of intelligent technologies.

Traditionally, quasi-static predefined set of rules (or policies) are stored in the LTE network devices. For example, the handoff process will be triggered once the RSRP of serving cell below a certain level for a period of time without considering other factors (such as network load and interference states) in network. The rule-based system is simple and convenient to implement. However, they cannot be changed with respect to the dynamically changing wireless environment; therefore the real performance could not reach the optimal ideal performance. For instance, the propagation channels, spectrum availability, topology, and interference are uncertain factors that are too complex to solve by static algorithm. Hence, the idea of incorporate artificial intelligence into the LTE system design arose gradually. As a way to realize artificial intelligence, machine learning uses various algorithms to train the massive dataset, learn from it, and then make decisions and predict events in the real world, so that optimal or near-optimal performance can be achieved. Figure 1 shows the good features of machine learning which can benefit the LTE networks.

• Intelligent Decision in Complex Problem

Decision-making is selecting a course of action from among available alternatives. There exist many complex decision problems in LTE system. The mobility of mobile devices and the dynamic nature of wireless channel result in the highly dynamic

Survey on Machine-Learning Techniques in LTE Networks, Fig. 1

Good features of machine learning that can benefit LTE networks application

environments and complicated management of spectrum access, radio resource, and so on. The highly complex nature of aforementioned problems in LTE system often means that inventing specific algorithms that will solve them perfectly every time is impractical, if not impossible. For example, the access control mechanism in HetNet directly influences the capacity of the cell. The typical factors that need to be considered in access control algorithms include the number of user equipments (UEs) with various QoS classes, channel quality indicator (CQI), resource allocation, and QoS requirements of different UEs. To achieve optimal performance, smart access control algorithm should automatically adjust according to the influent factors.

- **Data Classification/Cluster**
Classification and clustering are both methods that divide the data into classes based on similarity in the data. The difference is that classification is a kind of supervised learning with labeled training data, for example, spam/non-spam or fraud/non-fraud. The decision being modeled is to assign labels to new unlabeled pieces of data. This can be thought of as a dis-

crimination problem, modeling the differences or similarities between groups. On the other side, as unsupervised learning, data in clustering is not labeled but can be divided into groups based on similarity and other measures of natural structure in the data. In practical, many kinds of data generated in LTE system need to be classified or grouped for specific purposes, such as channel measurement report used for state feedback and description.

- **Prediction**
Prediction is estimating the value of a variable based on the value of another variables. The stronger the relationship between the variables, the more accurate the prediction. Regression is one of the prediction techniques based on correlation. Typical examples that are easy to understand are time series data like the price of a stock over time, the decision being modeled is what value to predict for new unpredicted data. The prediction of future data traffic requirement and mobility pattern based on historic data is very helpful for the operation of LTE system. For instance, the accurate prediction of future traffic and spectrum requirement would be helpful for

Survey on Machine-Learning Techniques in LTE Networks, Fig. 2 Machine-learning algorithms applicable to LTE

the intelligent spectrum allocation between multiple radio access technologies (RATs) such as GSM, UMTS, and LTE.

- **Relationship Discovery**
Data is used as the basis for the extraction of propositional rules. Such rules may, but are, typically not directed, meaning that the methods discover statistically supportable relationships between attributes in the data, not necessarily involving something that is being predicted. An example is the discovery of the relationship between the purchase of beer and diapers. In several operation processes of LTE system, there are many features that may influent the performance. However, generally the relationship between the features and the performance is not clear explicitly. With the help of machine-learning techniques, the inside relationship would be discovered and be used for optimizing the system performance.

Figure 2 shows the specific machine-learning algorithms applicable to long-term evolution.

Key Applications

LTE focuses on both performance requirements and efficiency requirements. Machine-learning techniques can be applied to both two areas to

improve the network performance and bring better user experience (UE). Machine learning has becoming a useful tool to solve complex problems in many fields. Meanwhile, many functions and implementations in LTE network require the assistance of intelligent technologies.

The performance requirement of LTE specify the peak data rate, mobility, latency, and so on. To satisfy these requirements, LTE developed many techniques which include RRM, CSI, channel prediction, traffic requirement prediction, and so on. The machine-learning algorithm which could bring network efficiency and intelligence is introduced to optimize the performance of the LTE system.

Table 1 summarizes the detailed application of machine learning in LTE network which shows the application areas, using machine-learning tools, and the purpose. It could help to sort out the skeleton of application of ML in LTE and make the structure clearer.

- **Resource Management**
Resource management in LTE is to provide high-quality service under the limited resources. The aim is to flexibly allocate and dynamically adjust the available resources of wireless network to maximize the utilization of resources. It includes power control, channel allocation, handover, scheduling, access control, load control, end-to-end QoS, and adaptive coding modulation. ML algorithms

Survey on Machine-Learning Techniques in LTE Networks, Table 1 Application of machine learning in LTE network

Applications		ML tools	Purpose
Resource management (performance)	Radio resource management	Q-learning, random neural network (RNN)	Adjust radio parameters to realize power control and decrease interference
	Access control/load balance	Feedforward neural network (FFNN), Q-learning	Decide whether to access certain eNodeB and decrease collision
	Handover	Self-organizing map (SOM), neural network, Q-learning	Learn the optimal handover parameters and decide to handover or not
	Channel state information (CSI)	Q-learning, neural network, support vector machine (SVM)	Optimize channel quality information (CQI) report way and even predict CQI
	Interference	Q-learning	Adjust power control parameters based on the environment to decrease interference
Prediction (performance)	Traffic load	K-means (KM), k-nearest neighbor (kNN)	Predict traffic and mobile data usage
	Channel quality	Random forest, neural network, regression tree	Predict channel quality and connectivity
Spectrum efficiency (efficiency)	Cognitive radio (CR)	Q-learning, artificial neural network (ANN), random neural network (RNN)	Determine the CR parameters by learning algorithms
Energy efficiency (efficiency)	Mobility terminals	Neural network, support vector regression (SVR)	Predict whether there will be control information to reduce the energy consumption of receiving control information
	eNodeB	Online Q-learning	Automatically switch on/off eNodeB
Security (efficiency)	SPAM/malware	Adaboost, Naive Bayes (NB), SVM	SPAM, malware detection

such as Q-learning, Neural Network could be used in Resource Management could increase the level of resource utilization (Kumar et al. 2013).

- Prediction

It is essential for people to employ prediction techniques in many areas such as mobile network traffic, throughput, and channel quality, so that users can get an increasing feel of satisfaction and the network runs more stable. To achieve these tasks, ML techniques such as k-nearest neighbor (kNN), k-means (KM), neural network, random forest, and other algorithms are used. By using these ML algorithms, the features of the network

could be determined, and then the prediction is made based on the features (Yue et al. 2017). Compared to tradition ways, the accuracy and efficiency of prediction are highly improved.

Efficiency requirements of LTE include the spectrum efficiency, energy efficiency, and even security management. This section will provide a detailed introduction of the machine-learning techniques using these techniques of enhancing system efficiency.

- Spectrum Efficiency

Since the increasing data rate in the radio network, more bandwidth is in need. However,

the spectrum is limited which requires more researches on new radio spectrum management pattern. Thus, many spectrum management patterns such as cognitive radio (CR) and other patterns based on prediction become more and more popular. However, the efficiency still needs to be improved to provide better service, so ML algorithms are introduced to this area. And usually, neural network algorithms could be used here, such as artificial neural network (ANN) and random neural network (RNN). ANN has been widely used in predicting in CR, and RNN has been proposed to achieve better generalization and to speed up the cognition process in LTE (Adeel et al. 2014). The results show that the network performance is greatly improved after the machine-learning algorithm is applied.

- **Energy Efficiency**

Due to the upsurge of traffic requirement as well as global energy resources shortage, energy saving in telecommunication systems attracts researchers' attention. Nowadays, energy saving could be realized by designing efficiency hardware, using renewable energy, and adopting efficiency resources allocation algorithm, base station sleeping mode techniques, and energy saving on mobile terminals. Since energy saving on mobile devices and base stations make no change on current network architecture and easy for implementation, so energy saving is usually realized by these two ways (Sue et al. 2016; Kong and Panaitopol 2013). ML algorithms could also be used here and usually help to optimize the network parameters to continuously adapt to the changing network traffic in deciding which action to take to minimize energy consumption.

- **Security**

Since the amount of data transferred in communication system is rising and the network environment is becoming complex, security in LTE network faces more and more challenge. Based on ML algorithms such as Adaboost, Naive Bayes (NB), and Support Vector Machine (SVM), the general action mode of different threats types could be

understood (Cao et al. 2017). This has been proved to help increase the accuracy of SPAM or malware detection in LTE network.

Future Directions

From the development of application of machine learning in LTE Networks, it appears that, in the future, emphasis will be given on three main directions. Firstly, future may focus on real-time decision instead of feature-based predictive applications. Thus, network nodes could make decisions based on real-time network conditions. Moreover, in the real world, human errors in data entry process, incorrect sensor reading, and software bug in data processing pipeline all could lead to missing values. Thus, secondly, the processing scheme for data sets with missing value may be paid more attention. Finally, overfitting problem occurs when the hypothesis becomes overly restrictive to obtain a consistent hypothesis. It is a general problem in machine learning, and it needs to be solved to obtain the nature rules of the data sets.

²Shanghai Jiao Tong University, Shanghai, China

Synonyms

Clock synchronization of nanomachines; Symbol synchronization of nanomachines; Time synchronization of nanomachines

Definitions

Synchronization refers to a process of establishing a relation among nanomachines on time scale, such that the nanomachines can synchronize their behaviors/actions coordinately. Clock/time synchronization of nanomachines refers to setting the clock of different nanomachines to realize the same time. Symbol synchronization of nanomachines refers to aligning the symbol interval, especially the start of the symbol, between the transmitter nanomachine and the receiver nanomachine.

Historical Background

Synchronization is an important and basic issue in molecular communication and its related applications. Different from using conventional electric or electromagnetic signal to carry information, molecular communication uses molecules to realize information carrying. This fundamental difference and its new application scenarios bring the synchronization issue many new problems and new challenges.

There are several kinds of concept of the synchronization among nanomachines: synchronization of oscillation, time/clock synchronization, and symbol synchronization.

For *synchronization of oscillation*, Abadal and Akyildiz have modeled a bacteria quorum-sensing mechanism, which forms the oscillation pattern for each nanomachine, and at the same time, these oscillation patterns are synchronized automatically under the quorum-sensing mechanism (Abadal and Akyildiz 2011). Different from (Abadal and Akyildiz 2011) which uses autoinducer molecules, Moore and Nakano have proposed another mechanism using inhibitory molecules to realize the similar oscillation and synchronization (Moore and Nakano 2013). Lin et al. have introduced an oscillation and synchronization model with one nanomachine having a repressing process module (Lin et al. 2016a).

For *time/clock synchronization*, the concept of the clock of the nanomachine has been mentioned in Nakano et al. (2014). Similar to electronic microprocessor, the clock of the nanomachine keeps track of time. A molecular phase-locked loop (PLL) has also been proposed in Lo et al. (2014) for regulating the clock. A typical clock synchronization scheme for diffusion-based molecular communication has been proposed in Lin et al. (2016b). A two-way message exchange mechanism is proposed for a Gaussian propagation delay model. The clock offset and clock skew are synchronized by maximum likelihood (ML) estimation. Later on, a series of variations are proposed. Different from previous literature, a high-efficiency blind synchronization scheme, which uses only one symbol transmission, is proposed in Luo et al. (2018). Least square method and single-input multiple-output (SIMO) design are proposed to estimate the propagation delay and further achieve the clock synchronization.

For *symbol synchronization*, Shahmohammadian et al. have proposed a blind ML criterion for estimating the channel propagation delay to achieve the symbol synchronization (ShahMohammadian et al. 2013). Jamali et al. have considered some practical challenges where the transmitter may not be equipped with internal clock and may not be able to emit molecules with a fixed frequency (Jamali et al. 2017). Synchronization-detection frameworks employing two types of molecules have been developed. Here the symbol synchronization refers to the estimation of the start of a symbol interval.

Foundations

The concept of the synchronization of nanomachines here includes three kinds of synchronization, i.e., synchronization of oscillation, time/clock synchronization, and symbol synchronization.

Synchronization of oscillation: This kind of synchronization originates from the quorum-sensing

mechanism in biology. In biology, quorum sensing is used by bacteria to regulate specific gene expression. In the field of molecular communication, nanomachines can adopt this mechanism or its variants to form a synchronized oscillation. An example is given below:

Example 1 It is assumed that the nanomachine can control the release of molecules and can sense the concentration of the molecules in its close environment. A loop can be established based on the following rules:

- If the sensed concentration is below certain threshold, the nanomachine will release a given amount of molecules.
- If the sensed concentration is above that threshold, the nanomachine will not release any molecules.
- The molecules diffuse away after releasing, so the concentration decreases. Once the concentration falls below the threshold, the above process will take place again.

The whole process can be represented by a finite-state machine (FSM) as shown in Fig. 1. “S_{off}” represents the nonactivated state, i.e., the nanomachine does not release molecules, while “S_{on}” represents activated state, i.e., the nanomachine releases molecules. If the sensed concentration reaches above the threshold, the state will change from S_{on} to S_{off}. If the sensed concentration falls below the threshold, the state will

Synchronization of Nanomachines, Fig. 1 State diagram for the FSM in the synchronization of oscillation. “S_{off}” and “S_{on}” represent the nonactivated and activated state. The state changes depending on the comparison result of the sensed concentration and the threshold

change from S_{off} to S_{on} , and the nanomachine will release an amount of molecules.

If there exist two or more nanomachines with the same working rules and use the same kind of molecules and they are close to each other under which condition the molecules released by one nanomachine can diffuse and arrive at other nanomachines, then eventually, the oscillations of these nanomachines will be synchronized.

Time/clock synchronization: Time/clock synchronization is essential for many applications. For example, the engineered nanomachines need a common clock so that they can release the antibody molecules at the same time to destroy tumors in the human body. In the data gathering application of the Internet of Nano Things (IoNTs), clock synchronization is the basis for interpreting the sensed data.

For different molecular communication channels and systems, different time/clock synchronization methods will be used. Two examples are provided below:

Example 2 The reference nanomachine sends its own clock reading to another nanomachine, which updates its clock once the clock reading is received using the following equation

$$T_{\text{rx}} = T_{\text{tx}} + t_{\text{delay}}, \quad (1)$$

where T_{tx} is the molecule releasing time instant based on the clock of the transmitter. The M -ary molecular shift keying (MoSK) is used to embed the clock reading into the molecule (Kim and Chae 2013). Here the time duration for synthesizing molecule is ignored. The key for the clock synchronization is to calculate the propagation delay t_{delay} .

The channel impulse response (CIR) in a 3D free diffusion environment without drift can be expressed as

$$N(t) = \frac{V_R Q}{(4\pi D t)^{3/2}} \exp\left(-\frac{d^2}{4Dt}\right), \quad (2)$$

where $N(t)$ represents the average number of observed molecules at time t , d is the distance from the transmitter to the receiving antenna, D is the diffusion coefficient, V_R is the volume of the spherical receiving antenna, Q is the number of released molecules.

t_{delay} is defined as the peak concentration time. In the absence of noise, t_{delay} can be derived from (2) as

$$t_{\text{delay}} = \frac{d^2}{6D}. \quad (3)$$

In case that d and D are known, t_{delay} can be directly calculated by (3). In case that d and D are unknown, the sampled concentration signals are used to estimate d and D which are further used to calculate t_{delay} by (3). The detailed processes are as follows. Because the nanomachines are not synchronized, so (2) in the 3D free diffusion channel is modified as

$$N(t) = \frac{V_R Q}{(4\pi D(t - t_0))^{3/2}} \exp\left(-\frac{d^2}{4D(t - t_0)}\right), \quad (4)$$

where t is a time instant based on the receiver's system clock. The time instant for molecule releasing based on the receiver's system clock is t_0 . Because there are limited unknowns in (4), so if enough samples are taken, then the unknowns can be calculated. And further t_{delay} can be estimated. According to (1), the receiver calculates T_{rx} and updates its clock value with it.

Example 3 In this example, the propagation delay (i.e., molecule arrival time) is not constant but a random variable because the channel is an inverse Gaussian channel in this case. Therefore, statistical methods can be used to estimate the clock offset (and clock skew if needed) between the nanomachines, so that they can update their clocks to achieve the clock synchronization.

Assuming that in a 1D drift channel, the transmitter sends its clock reading $T_{\text{tx},i}$ immediately into the channel with a molecule. MoSK is used to embed the clock reading into the molecule. Once receiving the molecule, the receiver records

its own clock reading $T_{rx,i}$ which is

$$T_{rx,i} = T_{tx,i} + t_i + \theta, \quad (5)$$

where t_i is propagation delay for the i th message transmission, which is a random variable. θ is the clock offset between the two nanomachines, which needs to be estimated.

It is known that the propagation delay t_i of the molecule in a 1D drift channel follows an inverse Gaussian distribution (Srinivas et al. 2012). The probability density function (PDF) can be expressed as

$$f(t_i; \mu, \lambda) = \left(\frac{\lambda}{2\pi t_i^3} \right)^{1/2} \exp \frac{-\lambda(t_i - \mu)^2}{2\mu^2 t_i}, \quad (6)$$

where μ and λ are related to the channel parameters which are assumed to be known by the nanomachine. After N message transmissions in total shown in Fig. 2, $\{T_{tx,i}, T_{rx,i}\}_{i=1}^N$ is obtained. Then based on the recorded time stamps $\{T_{tx,i}, T_{rx,i}\}_{i=1}^N$ and the PDF, one can use the ML estimation to estimate the clock offset θ , which can be expressed by

$$\hat{\theta} = \arg \max_{\theta} [\ln L(\theta; \{T_{tx,i}, T_{rx,i}\}_{i=1}^N)]. \quad (7)$$

where $L(\cdot)$ is likelihood function.

The ML method in Example 3 is suitable for the case where the PDF of the propagation delay and the system parameters in the PDF are known. If the PDF of the propagation delay is unknown but the CIR is known, then the method in Example 2 can be used for the time synchronization.

Symbol Synchronization the aim of the symbol synchronization is to align symbols between the transmitter and the receiver so that the receiver can correctly make signal detection. Two examples are provided to explain the symbol synchronization in molecular communication systems.

Example 4 (ShahMohammadian et al. 2013) : In this example, MoSK is adopted, meaning that different molecules are used to represent different symbols. Because different molecules have different diffusion coefficient, the peak concentration time, which is defined as the propagation, will be different. It will be better to estimate this peak concentration time correctly and then take sample at the peak concentration to make decision for the signal detection. The peak concentration has the largest signal-to-noise ratio (SNR) among all possible samples. The estimation of the peak concentration time based on the received signal is considered as the process of the symbol synchronization.

Synchronization of Nanomachines, Fig. 2 Message exchange mechanism for diffusion-based clock synchronization. The transmitter sends synchronization molecules

with the period of T . For the i th round, the transmitter records the molecule releasing time instant $T_{tx,i}$, and the receiver records the receiving time instant $T_{rx,i}$

Example 5 (Jamali et al. 2017) : In this example, more practical challenges are considered. In the practical conditions, the transmitter may not be equipped with an internal clock and may not be able to emit molecules with a fixed release frequency. The released time, which is considered as the start of the symbol interval, varies according to the availability of food and energy for molecule generation, the process for molecule production, etc. How to estimate the start of a symbol interval is the issue of the symbol synchronization, which is needed for reliable detection (Jamali et al. 2017).

For both of the above two examples, ML method can be used for the symbol synchronization. A general description of the ML method for the symbol synchronization is as follows. It is assumed that $s(t)$ is the transmitted signal, $z(t)$ is the received signal, and ζ is the unknown parameter which needs to be estimated for the symbol synchronization. ζ can be either the peak concentration time (i.e., propagation delay) in Example 4 or the start time instant of a symbol interval Example 5. The metric $\Lambda_{ML}(\zeta)$ is the probability function of the received signal given the unknown, as

$$\Lambda_{ML}(\zeta) = p(z(t); \zeta). \quad (8)$$

An estimate of the unknown ζ_{est} can be expressed as

$$\zeta_{\text{est}} = \arg \max_{\zeta} \Lambda_{ML}(\zeta). \quad (9)$$

Key Applications

Different types of synchronizations of nanomachines have different application scenarios. The synchronization of oscillation and time/clock synchronization can be involved in the scenarios of the coordination of the nanomachines (i.e., nanorobots), where the nanomachines need to coordinate their behaviors such as simultaneous drug releasing. The time/clock synchronization is necessary and essential in the IoNT scenarios.

The symbol synchronization is the basis for the data transmission/communication between nanomachines.

Future Directions

There are still some challenges for the synchronization of nanomachines if more complicated or more practical scenario is taken into account. Two examples are listed below:

- The synchronization issue for the mobile molecular communication system is a challenge and has not been investigated. In that system, due to the motion of the nanomachines, the propagation delay becomes a random variable, which makes the synchronization difficult.
- A blood vessel channel is a realistic channel which is one of the potential scenarios for the molecular communication. The feature of the blood velocity makes the channel a time-varying channel, i.e., the CIR is dependent on the molecule releasing time. In this case, the realization of the synchronization becomes a challenge.

[Primary synchronization signal sequences](#)

Definitions

The primary synchronization signals in LTE are used to help user equipments achieve the time and frequency synchronization.

Historical Background

Cell search is an important procedure to establish the connection between enhanced NodeB (eNB) and user equipment (UE) before data transmission and reception in long-term evolution (LTE) standard specified by 3GPP (2017). Initial synchronization and cell identity (ID) identification can be achieved by the use of synchronization signals transmitted by eNBs. LTE provides the primary synchronization signal (PSS) and the secondary synchronization signal (SSS) to help UEs perform the timing and frequency synchronization as well as the cell ID detection. There are a total of 504 physical layer cell IDs in LTE networks (3GPP 2017). They are divided into 168 group IDs, denoted by $N_{ID}^{(1)}$, and each group contains 3 sector IDs, denoted by $N_{ID}^{(2)}$. The cell ID N_{ID}^{cell} is then given by

$$N_{ID}^{cell} = 3N_{ID}^{(1)} + N_{ID}^{(2)} \quad (1)$$

where $N_{ID}^{(1)}$ ranges from 0 to 167 and $N_{ID}^{(2)}$ ranges from 0 to 2. Three different Zadoff-Chu (ZC) sequences are used in PSSs to represent three different sector IDs, while Gold sequences are employed for SSSs.

Key Applications

The primary synchronization sequences can be used for time synchronization and frequency offset estimation and cell ID detection in the cell search procedure.

Zadoff-Chu Sequences

Zadoff-Chu sequences are named after Zadoff (Frank and Zadoff 1962) and Chu (1972), which are also called Frank-Zadoff-Chu (FZC) sequences. The ZC sequences have been widely used in LTE including PSSs, random access preambles, uplink reference signals, and physical uplink control channels (PUCCHs). Since ZC sequences have constant amplitudes and ideal

periodic autocorrelations, they are also referred to as constant amplitude zero autocorrelation (CAZAC) sequences. The properties of ZC sequences will be given later. A ZC sequence of length N_{ZC} can be defined as (Chu 1972).

$$x_u[n] = \begin{cases} e^{-j\frac{\pi un^2}{N_{ZC}}}, & \text{even } N_{ZC}; \\ e^{-j\frac{\pi un(n+1)}{N_{ZC}}}, & \text{odd } N_{ZC}, \end{cases} \quad (2)$$

for $n = 0, 1, \dots, N_{ZC} - 1$, where u is called the root index and is relatively prime to N_{ZC} , that is, $\gcd(u, N_{ZC}) = 1$. Some major properties of ZC sequences are given as follows:

Property 1

For any sequence $s = (s[0], s[1], \dots, s[L-1])$ of length L , the periodic autocorrelation at displacement p is defined as

$$\rho(s; p) = \sum_{k=0}^{L-1} s[(k+p) \bmod L] s^*[k], \quad (3)$$

for $p = 0, 1, \dots, L-1$

where $(k+p) \bmod L$ denotes the modulo- L addition of k and p and $(\cdot)^*$ denotes the complex conjugate.

For an ZC sequence $x_u = (x_u[0], x_u[1], \dots, x_u[N_{ZC}-1])$ of length N_{ZC} , it has ideal periodic autocorrelation (Frank and Zadoff 1962; Chu 1972), that is,

$$\rho(s; p) = \begin{cases} N_{ZC}, & p = 0; \\ 0, & p = 1, 2, \dots, N_{ZC} - 1. \end{cases} \quad (4)$$

In addition, the amplitude $|x_u[n]| = 1$ for all n , and hence the ZC sequence has the CAZAC property.

Property 2

For odd-length N_{ZC} , two ZC sequences with root indices u and $N_{ZC}-u$ have the complex conjugate property (Popovic and Berggren 2008):

$$x_{N_{\text{ZC}}-u}[n] = x_u^*[n], \quad \text{for } n = 0, 1, \dots, N_{\text{ZC}} - 1. \quad (5)$$

Therefore, the ZC sequence with root index $N_{\text{ZC}} - u$ can be easily obtained from $x_u[n]$.

Property 3

A ZC sequence of odd length is centrally symmetric (Popovic and Berggren 2008):

$$x_u[N_{\text{ZC}} - 1 - n] = x_u[n], \quad \text{for } n = 0, 1, \dots, (N_{\text{ZC}} - 1)/2. \quad (6)$$

Property 4

For two odd-length ZC sequences with different root indices u_1 and u_2 , they have the theoretical minimum cross-correlations (Sarwate 1979) $\sqrt{N_{\text{ZC}}}$ if $|u_1 - u_2|$ is relatively prime to N_{ZC} . That is, the absolute value of the cross-correlation function of $x_{u_1}[n]$ and $x_{u_2}[n]$ at shift p is obtained by (Popovic 1992)

$$\begin{aligned} & |\rho(\mathbf{x}_{u_1}, \mathbf{x}_{u_2}; p)| \\ &= \left| \sum_{k=0}^{N_{\text{ZC}}-1} x_{u_1}[(k+p) \bmod N_{\text{ZC}}] x_{u_2}^*[k] \right| \\ &= \sqrt{N_{\text{ZC}}}, \quad \text{for } p = 0, 1, \dots, N_{\text{ZC}} - 1. \end{aligned}$$

Considering a special case with a prime number N_{ZC} , any two distinct sequences of the set of $N_{\text{ZC}} - 1$ ZC sequences with root indices $u = 1, 2, \dots, N_{\text{ZC}} - 1$ have low and constant cross-correlations.

Property 5

If the sequence length N_{ZC} is a prime, there is a remarkable discrete Fourier transform (DFT) property of the ZC sequence. For a ZC sequence $x_u[n]$ with root index u , the N_{ZC} -DFT of $x_u[n]$ denoted by $X_u[n]$ can be expressed as a weighted, conjugated, and time-scaled version of $x_u[n]$ (Beyme and Leung 2009):

$$X_u[n] = x_u^*[u^{-1}n]X_u[0] \quad (7)$$

where u^{-1} is the modular multiplicative inverse of u , that is, $u^{-1}u \equiv 1 \pmod{N_{\text{ZC}}}$. Therefore, DFT operation is not required to obtain the DFT of a ZC sequence. It can be seen that $X_u[n]$ also has constant amplitudes.

Primary Synchronization Signals

The PSSs use three 63-length ZC sequences with root indices 25, 29, and 34 to represent the sector IDs $N_{\text{ID}}^{(2)} = 0, 1$, and 2, respectively (3GPP 2017). Since the ZC sequences are employed in the frequency domain with center element nulled to avoid the effect of DC offset, the primary synchronization sequence is generated as below:

$$d_u[n] = \begin{cases} e^{-j\frac{\pi u n(n+1)}{63}}, & \text{for } n=0, 1, \dots, 30; \\ e^{-j\frac{\pi u(n+1)(n+2)}{63}}, & \text{for } n=31, 32, \dots, 61. \end{cases} \quad (8)$$

And the sequence is mapped to the center 62 subcarriers skipping the DC subcarrier. That is, the k th subcarrier $a[k]$ is assigned by

$$a[k] = d_u[n], \quad \text{for } n = 0, 1, \dots, 61 \quad (9)$$

with

$$k = n - 31 + \left\lfloor \frac{N_{\text{RB}}^{\text{DL}} N_{\text{SC}}^{\text{RB}}}{2} \right\rfloor \quad (10)$$

where $N_{\text{RB}}^{\text{DL}}$ denotes the number of resource blocks (RBs) for downlink (DL) transmission and $N_{\text{SC}}^{\text{RB}}$ denotes the number of subcarriers in one RB. Six center RBs are reserved for PSSs on specified OFDM symbols, so there are 72 reserved subcarriers, while the sequence length of $d_u[n]$ is only 62. One major reason to use 63-length ZC sequence is that 64-point fast Fourier transform (FFT) with lower complexity can be adopted. Moreover, the sequence length is taken as an odd prime number, so the primary synchronization sequences can possess Property 2, Property 3, Property 4, and Property 5 of ZC sequences. For Property 2, since the root indices

29 and 34 satisfy $34 = 63 - 29$, the equation $d_{34}[n] = d_{29}^*[n]$ can be utilized in sector ID detection algorithm. Property 4 enables UEs to detect the correct sector ID by finding the maximum correlations due to the low cross-correlations between different ZC sequences. Although Property 5 tells us that the inverse discrete Fourier transform (IDFT) of a ZC sequence has constant amplitudes, the IDFT size should be equal to the length of the sequence. Since 64-FFT with low complexity is preferred and the center element of the ZC sequence is nulled, the time-domain signal of a PSS by using 64-FFT does not have constant amplitudes anymore. Note that although the peak-to-average power ratio (PAPR) of a PSS is not 0dB, the PAPRs are still low (Tsai et al. 2007).

According to the good properties of ZC sequences, they have also been employed as synchronization sequences in narrowband Internet of Things (NB-IoT) (3GPP 2017). The primary and secondary synchronization signals use ZC sequences of lengths 11 and 131, respectively, in NB-IoT.

Definitions

This entry presents a practical three-dimensional (3D) outdoor-to-indoor channel model for multiuser massive multi-input multi-output (MU-massive MIMO). The model shows that the reflected clusters after passing through the boundary of the physical objectives from outdoor to indoor will be divided into several Ray paths, which results in different elevation/azimuth angles and phase excitation in all directions. The received spatial correlation is investigated based on the proposed 3D MU-massive MIMO. In addition, channel delay spread and multipath power delay profile (PDP) properties are studied based on the measured data. Finally, the result convinces that the proposed model is able to capture specific characteristic of outdoor-to-indoor 3D MU-massive MIMO.

Introduction

Recently, massive multi-input multi-output (MIMO) has attracted substantial research attentions as an important technique to address the demand for high data rate transmission. However, an accurate radio propagation model will be developed along the new technique.

The authors in 3GPP (July, 2015) provided an important example of the three-dimensional (3D) indoor hotspot channel model. This entry summarized the key results of indoor communications in addition to the outdoor contribution the 3rd Generation Partnership Project (3GPP) in Haneda et al. (2016b). In Weng et al. (2014), classified MIMO channels with a smaller number of antennas are investigated. Several experiments have been made to study the spatial correlation and the capacity indoor and outdoor-to-indoor environment in Kafle et al. (2008) and Kyritsi et al. (2003). In Kafle et al. (2008), for an instance, MIMO was designed for broadband MIMO channel sounding, capacity measurements, and characterizing the directional multipath of the radio propagation channel. In Kyritsi et al. (2003), the spatial correlation has been studied for in MIMO antenna system. In addition, the authors investigated an indoor 5G channel models for office and shopping mall environments in Haneda et al. (2016a). However, the impact of the elevation angles and the antenna element spacing for indoor 3D channel modeling was not considered in detail. In Yuan et al. (2015) and Renaudin et al. (2010), the work was based on the 3D theoretical channel model. The authors assumed an infinite number of effective scatters with resulting infinite complexity that can hardly be put into practical use. Furthermore, a novel 3D antenna polarized channel model was presented in Shafi et al. (2006). It investigated the impact of elevation angles for a MIMO system with a small number of antennas. Moreover, many researchers such as Dao et al. (2011) and Xu et al. (2004) investigated antenna configuration and polarization. A closed-form expression of the spatial correlation as a function of the physical parameters representing both characteristics of 3D MIMO was derived in Dao et al. (2011). Xu et al. (2004) presented a generalized MIMO channel modeling technique combining the spatial correlation and wave position in the direction of antenna arrays to achieve both accuracy and efficiency.

However, according to measurement observation in Payami and Tufvesson (2012), Gao et al. (2012), and Aghaeinezhadfirouzja et al. (2016, 2017), the abovementioned channel modeling

is not sufficient to accurately capture certain characteristics of 3D massive MIMO channels. Generally speaking, the previous researchers considered the channel modeling with a small number of antennas, indoor model with the impact on the horizontal or elevation angles by theoretical properties, not suitable to be directly applied to modeling 3D outdoor-to-indoor massive MIMO channels. In outdoor-to-indoor 3D massive MIMO environment, the clusters arrive from open to the close area passing through different scatters which will divided them into different Ray paths. Therefore, the Ray paths may obtain different elevation/azimuth angles based on their time delays and locations, where their angular of arrivals and departures need to be readdressed while generating the channel coefficients. Moreover, channels can vary with antenna configuration depending on the number of antenna elements used in massive MIMO system. It will then need properly model elevation angle of departures (EAoDs) and elevation angle of arrivals (EAoAs) as well as azimuth angle of departures (AAoDs) and azimuth angle of arrivals (AAoAs) of multipath components from the Ray paths that will help to contribute the spatial correlation among different antenna elements to the receivers (RXs). Therefore, to investigate the received spatial correlation, we considered antenna element space (AES) to recognize the antenna element location and the distance between two individual antenna elements for the correlation purposes.

In summary, we are introducing 3D outdoor-to-indoor channel models based on extensive measurements as well as preliminary result on channel parameters that are capable of capturing main properties of the 3D MU-massive MIMO.

The major contributions of this entry are the following:

1. In outdoor-to-indoor environments, the clusters arrive from open to close area passing through physical objectives on the outdoor-to-indoor boundaries, which will divide the clusters into several Ray paths and may provide new elevation and azimuth angles

toward different directions. This entry first proposes a 3D outdoor model and then based on the outdoor model; 3D indoor model has been investigated. And then, we investigate the characterization of the reflecting clusters which will be generated/regenerated to several multipath signals in 3D. So far, few works have been done on the generating/regenerating of the clusters to multipath.

2. An interesting interplay between vertical antenna pattern and elevation spread is observed with AES model that requires capturing the characteristics of elevation/azimuth angles for both vertical and horizontal directions of the antenna arrays. The goal of this part is also to provide different phase directions on received spatial correlation.
3. Statistical properties of the proposed model such as power delay profile (PDP) and delay spread (DS), including multipath richness and channel capacity/correlation of the 3D nonstationary channel model, were investigated. The proposed model is valid for outdoor-to-indoor communication in 3D MU-massive MIMO scenarios with the measured channel data.

Antenna Pattern

In this section, downlink 3D MU-massive MIMO system and polarization mixing were considered for outdoor-to-indoor situation. Massive MIMO antenna with pairs of cross-dipole elements with ± 45 degrees of polarization slant angle was installed at the transmitter (TX). Consider the polarized massive MIMO shown in Fig. 1, where (a) cross polarized (X-Pol) dipole elements at the TX, (b) is with vertical polarized (V-Pol) omnidirectional antenna elements at the RX, and (c) is the beam pattern coordinate system for 3D model.

Let us denote the elevation angle as θ and the azimuth angle as ϕ at the TX. Similarly ϑ is the elevation angle and φ is azimuth angle at the RX. The transmit massive MIMO antenna arrays are fixed at the $x - z$ plane both for transmitter and receiver. The minimal distances between antenna elements are d^{BS} and d^{UE} both for the TX and

Three-Dimensional Channel Measurement for the Indoor 5G Multiuser Massive MIMO System, Fig. 1 Two antenna patterns: 3D channel model of antenna elements in the hor-

izontal and vertical directions is indexed by (l, k) and (l', k') for (a) X-Pol and (b) V-Pol polarizations, respectively, and (c) beam pattern coordinate system for 3D model

the RX antennas, respectively. Denote l and k as the horizontal and the vertical indexes for $(l, k)_{th}$ of the transmit antenna elements, where $l = \{0, \dots, L-1\}$ and $k = \{0, \dots, K-1\}$, i.e., there are $L \times K$ pairs of transmit antenna elements.

Similarly, denote l' and k' as the horizontal and the vertical positions of the antenna elements, where $l' = \{0, \dots, L'-1\}$ and $k' = \{0, \dots, K'-1\}$, i.e., there are $L' \times K'$ pairs of antenna elements at the receiver. Let the location of the

$(0, 0)_{th}$ TX antenna element be the origin point O ; the location of the $(0, 0)_{th}$ receive antenna element is $(x_{(0,0)}, y_{(0,0)}, z_{(0,0)})$. Then we can determine the location and the distance of the other antenna elements to the $(0, 0)_{th}$ antenna element of the antenna array as follows.

Transmit Antenna Array

Then, the distance between the $(l, k)_{th}$ antenna element and the $(0, 0)_{th}$ antenna element at the transmitter can be computed as

$$d_{l,k}^{BS} = \sqrt{l^2 + k^2} \cdot d^{BS} \quad (1)$$

Moreover, vector $\mathbf{a}(\phi, \theta)_{l,k}$ is the array responses of the $(l, k)_{th}$ TX antenna element which is given by

$$\mathbf{a}(\phi, \theta)_{l,k} = e^{\left(\frac{2\pi}{\lambda} \hat{y} \cdot d_{l,k}^{BS}\right)} \quad (2)$$

where λ is the wavelength of the carrier frequency. $\hat{y} = [\sin \phi_{AOD} \cos \theta_{AOD}, \sin \phi_{AOD} \sin \theta_{AOD}, \cos \theta_{AOD}]$ is the outgoing wave direction.

Receive Antenna Array

Similarly, the distance between the $(l', k')_{th}$ antenna element and the $(0, 0)_{th}$ antenna element at the receiver can be computed as

$$d_{l',k'}^{UE} = \sqrt{l'^2 + k'^2} \cdot d^{UE} \quad (3)$$

The polarization vector at angle α from the z -axis in Fig. 1c has vertical and horizontal components of the antenna pattern, by expressing the response vector X in its ϑ and ϕ components which are proportional to Shafi et al. (2006)

$$\begin{aligned} X_{l',k'}^{UE} &= \begin{bmatrix} X_{l',k'}^{\vartheta} \\ X_{l',k'}^{\phi} \end{bmatrix} \\ &= \begin{bmatrix} \cos \alpha \sin \vartheta + \cos \alpha \cos \vartheta \cos \phi \\ \sin \alpha \cos \phi \end{bmatrix} e^{\left(\frac{2\pi}{\lambda} \hat{y}' \cdot d_{l',k'}^{UE}\right)} \end{aligned} \quad (4)$$

where X^{ϑ} and X^{ϕ} are the ϑ and ϕ polarized responses of the antenna at the direction of $\hat{y}' =$

$[\sin \phi \cos \vartheta, \sin \phi \sin \vartheta, \cos \vartheta]$ for the incoming wave in the response of the antenna. Therefore, the vector $\mathbf{a}(\varphi, \vartheta)_{l',k'}$ is the array response of the $(l', k')_{th}$ receive RX antenna element, and the $(0, 0)_{th}$ antenna element is given by

$$\begin{aligned} \mathbf{a}(\varphi, \vartheta)_{l',k'} &= \begin{bmatrix} \cos \alpha \sin \vartheta + \cos \alpha \cos \vartheta \cos \phi \\ \sin \alpha \cos \phi \end{bmatrix} \\ &e^{\left(\frac{2\pi}{\lambda} \hat{y}' \cdot d_{l',k'}^{UE}\right)} \end{aligned} \quad (5)$$

A Practical Model for Outdoor-to-Indoor Massive MIMO Systems

In this section, a 3D channel model for MU-massive MIMO is proposed, considering spherical wave front and cluster/Ray path evaluation in both time and array axes as shown in Fig. 2. The models are defined by two effective physical objectives, one around the TX and other one in the cube at the office/shopping mall around the RX. Prior to this, we assumed that the clusters reflect from different sides of the cube which are divided into several Ray paths that contribute different elevation/azimuth angles. In addition, we used a spherical model for dipole antennas for outdoor communication and a cube model for indoor communication to minimize clusters/Ray paths dispersing. The users are randomly located inside the cube. Some important characteristics of massive MIMO outdoor-to-indoor channel models are needed to be investigated, such as the distance between TX and RX, cluster appearance on the antenna array for outdoor situation, generating/regenerating of Ray path models for indoor situation, and Ray appearance on the RX antenna array.

Therefore, to generate the channel coefficient, three parts must be modeled when signals are traveling from the transmitter toward the receiver such as (a) toward the outdoor cluster, (b) toward the cube boundary (points), and (c) toward the receive antenna elements, respectively:

- Toward the outdoor cluster: Let us denote the $qt = \{1, \dots, Qt\}$, where Qt is equal to $\text{Cluster}_t = Qt(t' + \Delta t')$ as total clusters, in

which i'_{th} path from $(l, k)_{th}$ antenna element is added up with time $(t' + \Delta t')$. Prior to this, the first path from $(0, 0)_{th}$ antenna element with time t' is added up to the nearest cluster. And then, the rest of the paths from $(l, k)_{th}$ adjacent element are calculating with distance $d_{l,k}^{BS}$ which are added up with succeeding time instantaneously $(\Delta t')$ to the same cluster. The distance between the transmit antenna and the cube array is denoted by D .

- Toward the cube boundaries (points): q_{th} cluster is observable to the $q_c = \{1, \dots, Q_c\}$ cluster, where Q_c is equal to $\text{Cluster}_{cube} = Q_c(t')$ as total clusters at the cube boundary based on distance D between the transmit antenna array and the cube boundary. In addition, there are s_{th} points, where $s = \{1, \dots, S\}$ are randomly located on the cube boundaries in which the cluster is passing through them toward the receive antenna elements.
- Toward the receive antenna elements: q_{th} cluster after passing through s_{th} point will be divided into several Ray paths. As an example, cluster q_{c1} is divided to the q_{th} Ray path, where $q = \{1, \dots, Q\}$. Therefore, denote $\text{Ray}_r = Q_r(t' + \Delta t')$ as total Ray paths which are observed at the l', k' antenna elements, where first Ray path is arriving with time t' toward $(0, 0)_{th}$ antenna element and then the rest of the Ray paths are arriving with succeeding time instantaneously $(\Delta t')$ toward $(l', k')_{th}$ antenna element that is calculating with distance $d_{l',k'}^{UE}$. The distance between the receive antenna array and the cube array is denoted by D_c . Therefore, the total distances between the transmit antenna array and the receive antenna array can be calculated by $D' = (D + D_c, 0, 0)$.

A 3D Massive MIMO Channel for outdoor Scenario

To perform the evolution of outdoor channel coefficient, the clusters in the set of $(Q_t(t' + \Delta t') \cap Q_c(t'))$ are generated based

on the outdoor cluster evolution for outdoor communication. Based on the outdoor model, the multipath gain between the transmit antenna and the cube boundary will be denoted as (CI_n^{out}) which is the total number of clusters, where $n = 1, \dots, N$ cluster for outdoor communication that can be expressed as

$$CI_n^{\text{out}} = \text{card} \left(\bigcup_{l,k=1}^{L,K} \bigcup_{s=1}^S \left(Q_t(t' + \Delta t') \cap (Q_c(t')) \right) \right) \quad (6)$$

where the operator $\text{card}(\cdot)$ denotes the cardinality of a set (Wu et al. (2014, 2015)). The operator $\text{card } CI_n^{\text{out}}$, each cluster, says $\text{Cluster}_n (n = 1, \dots, CI_n^{\text{out}})$ is for outdoor models.

Based on the above analysis and the summary of key parameter definitions in Table 1, the massive MIMO channel matrix can be expressed as an $L, K \times S$ complex matrix $H(t', \Delta t', \tau) = [h_{l,k,s}(t' + \Delta t', \tau)]_{L,K \times S}$. The amplitude complex gains between the $(l, k)_{th}$ antenna elements at the L, K transmit antenna, s_{th} point at the cube boundary and the delay τ , can be represented as

$$H_{l,k,s}(r' + \Delta t', \tau) = \sum_{n=1}^{CI_n^{\text{out}}} H_{l,k,n,s}(r' + \Delta t') \delta(\tau - \tau_n) \quad (7)$$

The calculation of complex gains for outdoor model can be expressed as LOS and NLOS components.

1. NLOS, part (A): The $(l, k)_{th}$ transmit antenna element vectors $\mathbf{a}(\phi, \theta)_{l,k}$ obtained by Eq. (2) in Section “A 3D Massive MIMO Channel for outdoor Scenario” and the vector between n_{th} cluster via i'_{th} path can be presented as $D_{n,i',l,k}^{BS}(t' + \Delta t')$, and the vector between the n_{th} cluster and transmit antenna array is denoted by $D_n^{BS}(t')$ at the TX.

Three-Dimensional Channel Measurement for the Indoor 5G Multiuser Massive MIMO System, Table 1
Summary of key parameter definitions

Parameters	Values
$(\theta, \phi), (\vartheta, \varphi)$	Elevation and azimuth angles of the TX and RX arrays, respectively
$D_{n,i',l,k}^{BS}(t' + \Delta t'), D_{LOS,i',l,k}^{BS}(t' + \Delta t')$	Distance vector between n_{th} and LOS_{th} cluster and $(l, k)_{th}$ transmit antenna elements via i'_{th} path, respectively
$D_n^{BS}(t'), D_{LOS}^{BS}(t')$	Distance vector between n_{th} and LOS_{th} cluster and $(l, k)_{th}$ transmit antenna elements, respectively
$D_{n,s}^{cube}(t'), D_{LOS,s}^{cube}(t')$	Distance between s_{th} vector and n_{th}, LOS_{th} cluster at cube boundary, respectively
$D_{s,q,l',k'}^{UE}(t' + \Delta t'), D_{s,LOS,l',k'}^{UE}(t')$	Distance vector between q_{th} and LOS_{th} Ray path and $(l', k')_{th}$ receive antenna elements from s_{th} point, respectively
$D_{s,l',k'}^{UE}(t'), D_s^{UE}(t')$	Distance vector between q_{th} and LOS_{th} Ray path and $(l', k')_{th}$ receive antenna elements, respectively
$\mathbf{a}(\phi, \theta)_{l,k}, \mathbf{a}(\varphi, \vartheta)_{l',k'}$	Array response of the TX (X-Pol) and RX (V-Pol) polarization
$\rho_{l,k,l',k',n,s,q}, \rho_{l,k,l',k',s}$	Received spatial correlation function of the received signal both for NLOS and LOS components, respectively
$\Phi_q^{(v,v)}, \Phi_q^{(v,h)}, \Phi_q^{(h,v)}, \text{ and } \Phi_q^{(h,h)}$	Four random initial phases (vertical/vertical), (vertical/horizontal), (horizontal/vertical), and (horizontal/horizontal), respectively

$$\begin{aligned} [D_{n,i',l,k}^{BS}(t' + \Delta t')] &= D_n^{BS}(t') \\ \begin{bmatrix} \sin \phi_{n,i',l,k}^{AAoD}(t' + \Delta t'), \cos \theta_{n,i',l,k}^{EAoD}(t' + \Delta t') \\ \sin \phi_{n,i',l,k}^{AAoD}(t' + \Delta t'), \sin \theta_{n,i',l,k}^{EAoD}(t' + \Delta t') \\ \cos \theta_{n,i',l,k}^{EAoD}(t' + \Delta t') \end{bmatrix}^T &= \begin{bmatrix} \exp(j\Phi_n^{(v,v)}) & \sqrt{X^h} \exp(j\Phi_n^{(v,h)}) \\ \sqrt{X^v} \exp(j\Phi_n^{(h,v)}) & \exp(j\Phi_n^{(h,h)}) \end{bmatrix} \end{aligned} \quad (8)$$

Similarly, the s_{th} vector and n_{th} cluster in the direction of waves at the cube boundary can be presented as

$$[D_{n,s}^{cube}(t')] = \begin{bmatrix} \sin \phi_{n,s}(t'), \cos \theta_{n,s}(t') \\ \sin \phi_{n,s}(t'), \sin \theta_{n,s}(t') \\ \cos \theta_{n,s}(t') \end{bmatrix} + D \quad (9)$$

Then, the four random initial phases for n_{th} cluster are derived as

where $\sqrt{X^h}$ and $\sqrt{X^v}$ are inverse crosses polarized for X-Pol (vv/hv and hh/vh) transmission, respectively. $j = \sqrt{-1}$ and $\Phi_n^{(v,v)}, \Phi_n^{(v,h)}, \Phi_n^{(h,v)}, \Phi_n^{(h,h)}$ are the four random initial phases of different polarization combinations.

2. LOS, part (A): The $(l, k)_{th}$ transmit antenna element vectors $\mathbf{a}(\phi, \theta)_{l,k}$ and the vector between LOS_{th} cluster via i'_{th} path are denoted by $D_{LOS,i,l,k}^{BS}(t' + \Delta t')$, and the vector between the LOS_{th} cluster and the transmit antenna array is denoted by $D_{LOS}^{BS}(t')$ at the TX.

$$[D_{LOS,i',l,k}^{BS}(t' + \Delta t)] = D_{LOS}^{BS}(t') \begin{bmatrix} \sin \phi_{LOS,i',l,k}^{AAoD}(t' + \Delta t'), \cos \theta_{LOS,i',l,k}^{EAoD}(t' + \Delta t') \\ \sin \phi_{LOS,i',l,k}^{AAoD}(t' + \Delta t'), \sin \theta_{LOS,i',l,k}^{EAoD}(t' + \Delta t') \\ \cos \theta_{LOS,i',l,k}^{EAoD}(t' + \Delta t') \end{bmatrix}^T \quad (11)$$

Similarly, the distance s_{th} vector and LOS cluster vector at cube boundary in the direction of waves can be presented as

$$\begin{aligned} & [D_{LOS,s}^{\text{cube}}(t')] \\ &= \begin{bmatrix} \sin \phi_{LOS,s}(t'), \cos \theta_{LOS,s}(t') \\ \sin \phi_{LOS,s}^{AAoD}(t'), \sin \theta_{LOS,s}(t') \\ \cos \theta_{LOS,s}(t') \end{bmatrix} + D \end{aligned} \quad (12)$$

Then, the two random initial phases for outdoor $outLOS_{th}$ cluster is derived as

$$\begin{bmatrix} \exp(j\Phi_{outLOS}^{(v,v)}) & 0 \\ 0 & \exp(j\Phi_{outLOS}^{(h,h)}) \end{bmatrix} \quad (13)$$

where $\Phi_{outLOS}^{(v,v)}$ and $\Phi_{outLOS}^{(h,h)}$ are two random initial phases of different polarization combinations.

Next, let us denote Rician factor as G . Additionally, the power of the n_{th} cluster is defined as A_n . Therefore, a $\text{Clusters}_n \in (Qt(t' + \Delta t) \cap Qc(t')) \leq Cl_n^{\text{out}}$ is observed for outdoor model.

– if $\text{Clusters}_n \in \cup_{l,k=1}^{L,K} \cup_{s=1}^S (Qt(t' + \Delta t) \cap Qc(t'))$,

$$H_{l,k,s,n}(t' + \Delta t', \tau) =$$

$$\begin{aligned} & \left(\delta(n-1) \sqrt{\frac{G}{G+1}} [D_{LOS,i',l,k}^{BS}(t' + \Delta t')] \times \begin{bmatrix} \exp(j\Phi_{outLOS}^{(v,v)}) & 0 \\ 0 & \exp(j\Phi_{outLOS}^{(h,h)}) \end{bmatrix} \times [D_{LOS,s}^{\text{cube}}(t')] \right) \\ & \times \mathbf{a}(\phi, \theta)_{l,k} + \sqrt{\frac{A_n}{G+1}} \sum_{n=1}^N [D_{n,i',l,k}^{BS}(t' + \Delta t')] \times \begin{bmatrix} \exp(j\Phi_n^{(v,v)}) & \sqrt{X^h} \exp(j\Phi_n^{(v,h)}) \\ \sqrt{X^v} \exp(j\Phi_n^{(h,v)}) & \exp(j\Phi_n^{(h,h)}) \end{bmatrix} \\ & \times [D_{n,s}^{\text{cube}}(t') \times \mathbf{a}(\phi, \theta)_{l,k}] \end{aligned} \quad (14)$$

– If $\text{Clusters}_n \notin \cup_{l,k=1}^{L,K} \cup_{s=1}^S (Qt(t' + \Delta t') \cap Qc(t'))$,

$$Cl_q^{\text{in}} = \text{card} \left(\cup_{s=1}^S \cup_{l',k'=1}^{L',K'} (Qc(t') \cap Qr(t' + \Delta t)) \right) \quad (16)$$

$$H_{l,k,s,n}(t' + \Delta t', \tau) = 0 \quad (15)$$

and the total number of clusters/Ray paths in Eqs. (6) and (16) for outdoor-to-indoor communications is derived as

$$Cl_{n,q}^{\text{Total}} = (Cl_n^{\text{out}} \cup Cl_q^{\text{in}}) \quad (17)$$

A 3D Massive MIMO for Outdoor-to-Indoor Scenario

In addition, to perform the evolution of channel coefficient for indoor communication, the Ray paths in the set $(Qc(t') \cap Qr(t' + \Delta t'))$ are generated based on the outdoor cluster after passing via s_{th} point and will be divided into the several Ray paths. Based on the indoor model, the multipath gain between cube boundary and the receive antenna elements, which will be denoted as (Cl_q^{in}) , is the total number of Ray paths on indoor communication that can be expressed as

where the operator $\text{card } Cl_q^{\text{in}}$, each Ray path, say $\text{Ray}_q (q = 1, \dots, Cl_q^{\text{in}})$, is for indoor models. Similarly, the massive MIMO channel matrix can be expressed as an $S \times L', K'$ complex matrix $H(t', \Delta t', \tau) = [h_{l,k,q}(t' + \Delta t', \tau)]_{S \times L', K'}$. The amplitude complex gains between the s_{th} point at the cube boundary and $(l', k')_{th}$ antenna elements at the L', K' receive antenna elements and delay τ can be represented as

$$H_{l',k',q}(t' + \Delta t', \tau) = \sum_{q=1}^{Cl_q^{in}} H_{l',k',q}(t' + \Delta t') \delta((\tau - \tau_q)(t')) \quad (18)$$

The calculation of complex gains for indoor model can expressed as LOS and NLOS components.

$$\left[D_{s,q,l',k'}^{UE}(t' + \Delta t') \right] = D_{q,l',k'(t')}^{UE} \begin{bmatrix} \sin \varphi_{s,q,l',k'}^{AAoA}(t' + \Delta t'), \cos \vartheta_{s,q,l',k'}^{AAoA}(t' + \Delta t') \\ \sin \varphi_{s,q,l',k'}^{AAoA}(t' + \Delta t'), \sin \vartheta_{s,q,l',k'}^{AAoA}(t' + \Delta t') \\ \cos \vartheta_{s,q,l',k'}^{AAoA}(t' + \Delta t') \end{bmatrix} + D_c \quad (19)$$

Then, the four random initial phases for indoor q_{th} Ray path are derived as

$$\begin{bmatrix} \exp(j\Phi_q^{(v,v)}) & \sqrt{X^h} \exp(j\Phi_q^{(v,h)}) \\ \sqrt{X^v} \exp(j\Phi_q^{(h,v)}) & \exp(j\Phi_q^{(h,h)}) \end{bmatrix} \quad (20)$$

where $\sqrt{X^h}$ and $\sqrt{X^v}$ are inverse polarizations in the cube. $j = \sqrt{-1}$ and $\Phi_q^{(v,v)}, \Phi_q^{(v,h)}$,

$$\left[D_{s,LOS,l',k'}^{UE}(t') \right] = D_s^{UE}(t') \begin{bmatrix} \sin \varphi_{s,LOS,l',k'}^{AAoA}(t' + \Delta t'), \cos \vartheta_{s,LOS,l',k'}^{AAoA}(t' + \Delta t') \\ \sin \varphi_{s,LOS,l',k'}^{AAoA}(t' + \Delta t'), \sin \vartheta_{s,LOS,l',k'}^{AAoA}(t' + \Delta t') \\ \cos \vartheta_{s,LOS,l',k'}^{AAoA}(t' + \Delta t') \end{bmatrix}^T + D_c \quad (21)$$

Then, the two random initial phases for indoor $inLOS_{th}$ Ray path are derived as

$$\begin{bmatrix} \exp(j\Phi_{inLOS}^{v,v}) & 0 \\ 0 & \exp(j\Phi_{inLOS}^{h,h}) \end{bmatrix} \quad (22)$$

1. NLOS, part (B): The $(l', k')_{th}$ receive antenna element vectors on polarization of $\mathbf{a}(\varphi, \vartheta)_{l',k'}$ obtained by Eq. (5) and the vector between q_{th} Ray path through s_{th} point can be denoted as $D_{s,q,l',k'}^{UE}(t' + \Delta t')$. Furthermore, the vector between the q_{th} Ray path and the receive antenna array is denoted by $D_{q,l',k'}^{UE}(t')$.

2. LOS, part (B): Similarly, the $(l', k')_{th}$ receive antenna element vectors for antenna polarization $\mathbf{a}(\varphi, \vartheta)_{l',k'}$ obtained by Eq. (5) and the vector between the LOS_{th} Ray path via s_{th} point can be denoted as $D_{s,LOS,l',k'}^{UE}(t' + \Delta t')$. Furthermore, the vector between the receive antenna array and s_{th} point is denoted by $D_s^{UE}(t')$.

where $\Phi_{inLOS}^{(v,v)}, \Phi_{inLOS}^{(h,h)}$ are random initial phases of different polarization combinations.

Therefore, a $\text{Ray}_q \in (Qc(t'), Qr(t' + \Delta t) \leq Cl_q^{in} \leq Cl_{n,q}$ is observed for indoor model.

If $\text{Ray}_q \in \cup_{s=1}^S \cup_{l',k'=1}^{L',K'} (Qc(t') \cap Qr(t' + \Delta t'))$,

$$H_{l',k',s,q}(t' + \Delta t', \tau) = \left(\begin{aligned} & \delta(q-1) \sqrt{\frac{G}{G+1}} \left[D_{s,LOS,l',k'}^{UE}(t') \right] \times \begin{bmatrix} \exp(j\Phi_{LOS}^{v,v}) & 0 \\ 0 & \exp(j\Phi_{inLOS}^{h,h}) \end{bmatrix} \times \left[D_{inLOS,s}^{\text{cube}}(t') \right] \\ & \times \mathbf{a}(\varphi, \vartheta)_{l',k'} + \sqrt{\frac{A_q}{G+1}} \sum_{q=1}^Q \left[D_{s,q,l',k'}^{UE}(t' + \Delta t') \right] \times \begin{bmatrix} \exp(j\Phi_q^{(v,v)}) & \sqrt{X^h} \exp(j\Phi_q^{(v,h)}) \\ \sqrt{X^v} \exp(j\Phi_q^{(h,v)}) & \exp(j\Phi_q^{(h,h)}) \end{bmatrix} \\ & \times \left[D_{n,s}^{\text{cube}}(t') \right] \times \mathbf{a}(\varphi, \vartheta)_{l',k'} \end{aligned} \right) \quad (23)$$

$$\begin{aligned}
& - \text{ If } \text{Ray}_q \notin \cup_{s=1}^S \cup_{l',k'=1}^{L',K'} (Qc(t') \\
& \cap Qr(t' + \Delta t')), \\
& H_{l',k',s,q}(t' + \Delta t', \tau) = 0
\end{aligned} \quad (24)$$

where the power of the q_{th} Ray path is defined as A_q . In the case of indoor communication, which is in the close area, one can assume that $G = \infty$, and for the case which is close to the window, a reasonable value for G is -4 dB Knudsen and Pedersen (2002).

Channel Properties

For the proposed 3D MU-massive MIMO, statistical properties will be derived in this section, i.e., received spatial correlation, multipath delay properties, and channel capacity. Here, we focused on the downlink channel model to quantify the effect of correlation and measure the performance gains realizable through potential elevation at the RX.

Outdoor-to-Indoor Multipath Delay Properties

In this subsection, multipath delay properties are proposed based on the 3D models. In this model, we assumed that there are two parts to investigate the delay properties, one for outdoor situation, from the TX toward the cube, and the other one is from the cube toward the users. We considered cluster and multipath time delays which are reflection with the delay of τ , each with the same power in indoor channel models. It is observed from indoor channel measurements that different clusters are divided into several multiple Ray paths and the arrival time clusters follow an individual Poisson process with the delay of each path spaced in an arbitrary manner. The arrival time of Ray in n_{th} cluster, denoted by T_n , is modeled by a Poisson process which is derived in Cho et al. (2010)

$$\begin{aligned}
f_{T_n}(T_n | T_{(n-1),n}) &= \Lambda \exp[-\Lambda(T_n - T_{(n-1)})], \\
n &= 1, 2, \dots
\end{aligned} \quad (25)$$

$$\begin{aligned}
f_{\tau_{q,n}}(\tau_{q,n} | \tau_{(q-1),n}) &= b \exp \\
&[-B(\tau_{q,n} - \tau_{(q-1),n})], \quad (26) \\
q &= 1, 2, \dots
\end{aligned}$$

where Λ and b are average arrival rate of cluster and Ray in each cluster, respectively. The $\tau_{q,n}$ denotes the arrival time of n_{th} cluster to the q_{th} Ray path. The arrival time of the n_{th} cluster, τ_n , is defined as the arrival time of the n_{th} cluster T_n .

Received Spatial Correlation and Capacity

In practice, the channels between the different antenna elements are often correlated, and therefore, the potential multiple antenna gains may not always be attainable (Wang and Murch (2006)). We focused and analyzed the spatial correlation of the RX, including the effect of antenna polarization based on the practical multipath indoor wireless communication environment. We will then investigate and minimize such correlation at the RX by considering the AES to recognize the antenna element and its adjacent antenna elements. Because of this, we developed received spatial correlation based in Cho et al. (2010). $\alpha_{n,q}$ and $\beta_{n,q}$ denote the amplitude and phase of q_{th} Ray path for v polarized antennas. Here, the received spatial correlation between two antenna elements via q_{th} path and the n_{th} cluster can be represented for both

$$H1_{l,k,l',k',n,s,q}(t' + \Delta t', \tau) = \alpha_q e^{j\beta_q} \sqrt{P}(\varphi, \vartheta) \quad (27)$$

$$\begin{aligned}
H2_{l,k,l',k',n,s,q}(t' + \Delta t', \tau) \\
= \alpha_q (\mathbf{a}(\varphi, \vartheta)_{l',k'} + \beta_q) \sqrt{P}(\varphi, \vartheta)
\end{aligned} \quad (28)$$

where $\sqrt{P}(\varphi, \vartheta)$ denotes the power angular spread.

However, the time difference between $H1$ and $H2$ as shown in Eqs. (27) and (28) and the following received spatial correlation function for the SULA with time instant t where all sub-Rays have equal power which can be expressed as

$$\rho_{l,k,l',k',n,s,q}(\lambda; t) = E \left[\frac{H1_{l,k,l',k',n,s,q}(t) H2_{l,k,l',k',n,s,q}^*(t)}{H1_{l,k,l',k',n,s,q}(t) H2_{l,k,l',k',n,s,q}^*(t)} \right] \quad (29)$$

As the result, the received spatial correlation can be rewritten as the sum of received spatial correlation of the *LOS* component $\rho_{l,k,l',k'}^{LOS}(\lambda; t)$ and the received spatial correlation of the *NLOS* components $\rho_{l,k,l',k',s}^{NLOS}(\lambda; t)$

$$\begin{aligned} \rho_{l,k,l',k',n,s,q}(\lambda; t) &= \rho_{l,k,l',k',s}^{LOS}(\lambda; r) \\ &+ \rho_{l,k,l',k',n,s,q}^{NLOS}(\lambda; t) \end{aligned} \quad (30)$$

For the received spatial correlation of the *LOS* component,

$$\rho_{l,k,l',k',s}^{LOS}(\lambda; r) = \frac{G}{G+1} \times e^{(j \frac{2\pi}{\lambda} \cdot d_{l',k'}^{UE} - \frac{2\pi}{\lambda} \cdot d_{l',k'}^{UE})} \quad (31)$$

In addition, the received spatial correlation among channel coefficient is fully characterized by the correlation matrix. Under the assumption, the ergodic channel capacity C for different polarization antennas, with their signal-to-noise ratio (SNR), is computed by using the following expression:

$$SNR = \frac{H^T H}{\sigma_n^2} \quad (32)$$

where σ_n^2 is the noise variance and H is the normalized channel matrixes, where channel capacity can be computed as

$$C = \log_2 [\det(I + SNR)] \text{ bps/Hz} \quad (33)$$

where $\det(\cdot)$ denotes the determinant and I is the identity matrix.

An Experimental Result and Discussion

This section provides the result of the real scenario of the proposed model from the measured data. An investigation has been made to study full characterization through a practical on 3D MU-massive MIMO systems, at Shanghai Jiao Tong University (SJTU) campus network, as shown in Fig. 3. UEs, each has omnidirectional elements, were utilized at the RXs. The location of UE1 is near the window, while UE2 and UE3 are in the same floor but both far from the window. The BS height about 35 m from the ground and the receiver antenna's heights in all UEs are 30 m in the office. The distribution of azimuth and elevation angles at the TX and RX has been studied, where azimuth and elevation angles are reflected in different directions from outdoor-to-indoor communications.

To perform our proposed model, delay properties and channel capacity/correlation of clusters/Ray paths were investigated according to the measured data and proposed model. The result was based on EAoA (ϑ), AAoA (φ), n_{th} cluster, (q_{th}) Ray path, element spacing, and the antenna polarization. Consequently, as shown in the following figures, we also investigated the performance of channel modeling with the effect of dual antenna polarization antenna. This observation also was from the dynamic property of clusters on the array axis which may observe different Ray paths with different (ϑ , φ) to the Rx.

Due to the presence of multiple electromagnetic paths at the RX side, more than one pulse is received. Figure 4 shows the time-domain channel coefficients between TX and UE1 which are generated by the time-domain models for proposed 3D MU-massive MIMO channel. As shown in the figure, path 1 is the *LOS* Ray path and the other are reflected paths. We proposed that a reflected cluster from physical objective be divided into several Ray paths which are observable to the user where he/she is located inside the cube. It is illustrated that the channel gain is time-varying with the amplitude and phase, demonstrating the fading characteristics.

Three-Dimensional Channel Measurement for the Indoor 5G Multiuser Massive MIMO System, Fig. 3 Overview of the measurement area at the campus of Shanghai Jiao Tong University, China. A spaced rectangular antenna array with cross polarized patch

antenna elements at the TX was placed on the rooftop of the biomedical building during their respective measurement campaigns and the spaced uniform linear array as users were located inside the SEIEE building acting as multiple-antenna user

Three-Dimensional Channel Measurement for the Indoor 5G Multiuser Massive MIMO System, Fig. 4 Time-domain channel characteristic

In conventional indoor MIMO channel models, the total paths are not sufficient to represent the properties of the reflected cluster, because of the noncooperative situation in elevation angles as well as their properties like delay and capacity correlation which should be considered and developed when calculating channel coefficient as shown in Section “A 3D Massive MIMO for Outdoor-to-Indoor Scenario”

In addition, the PDP, delay properties of arriving cluster and Ray paths of the proposed model over all snapshots, has been investigated. Figure 5a, b generated the corresponding delay on 3D channel model. The results were obtained by different Ray paths, one for a direct path with zero delay $\tau_1 = 0$ and the other paths which are reflection with the delay of $\tau_2 > 0$, each of them has the same power. On the other hand, Figure 5b

Three-Dimensional Channel Measurement for the Indoor 5G Multiuser Massive MIMO System, Fig. 5 (a) Ray path delay profile, (b) average channel power, (c) distribution of cluster arrival times, and (d) distribution of Ray arrival times

Three-Dimensional Channel Measurement for the Indoor 5G Multiuser Massive MIMO System, Fig. 6 Ergodic channel capacity correlation

shows an average channel power decreases exponentially with the channel delay. A plot indicates how a transmitted pulse decreases based on the PDP as it will travel through a multipath channel with different propagation delays. In addition, it is illustrated in Figs 5c, d that the delay profile of Ray arrival time with q_{th} Ray path of the $\tau_{q,n}$ in the n_{th} cluster and q_{th} Ray path is generated and that each of them has an exponential distribution of Eqs. (25) and (26). Furthermore, in the plot, the signal power of each multipath is plotted against their respective propagation delays, and the different propagation path lengths cause different propagation time delays. In addition, there might be some signals arriving at a certain delay, but after some time, the power significantly shuts down. If we look at the last arriving paths, they have very low power. They might be insignificant in the instance that the maximum DS is huge. They are very insignificant that it would not be well to consider such paths of low power in the DS.

Finally, we described the ergodic capacity correlation which resulted from the existing 3D channel model that was obtained from Eqs. (32) and (33). We focused and analyzed the ergodic capacity correlation of the RXs including the effect of antenna polarization based on practical multipath wireless communication environment obtained by Sect. IV. The correlation matrix for multiple antenna techniques has been defined

for the evaluation of the performance of the 3D MU-massive MIMO. Figure 6 shows the plot of ergodic correlation capacity between two antenna elements which are vertically polarized and another switching to horizontal polarization because the user movements in different directions have significant different capacity. It is illustrated that the antenna polarization mismatching with the direction of Ray paths is degrading the received channel capacity from time to time. Intuitively, the distance between two inter-elements are at maximum, while the correlation remains minimal. In other words, the channel capacity is varying based on the space between antenna elements increases.

Conclusion

In this entry, we proposed a 3D practical outdoor-to-indoor MU-massive MIMO by investigating the multipath delay including channel correlation and capacity, around Shanghai Jiao Tong University. This consists of defining a composite channel coefficient that is the scaled sums of 3D components were jointly calculated the azimuth and elevation angles for the proposed model. First, we modeled our outdoor channel coefficient and then Ray path model proposed from the reflected clusters which obtained different elevation/azimuth angles and phase excitations.

In addition, their impact on 3D MU-massive MIMO has been studied via statistical properties including received spatial correlation among the massive MIMO antennas. Furthermore, we investigated the essential channel characteristics, such as DS and PDP for different clusters and Ray paths. Finally, ergodic correlation capacity was computed as a function of correlation for multiple RX antennas.

OFDM synchronization

Definitions

Synchronization in OFDM systems means finding the timing and carrier frequency offset of observed OFDM signal.

Historical Background

Orthogonal frequency-division multiplexing (OFDM) has been widely adopted as a mature technique owing to its high data rate transmission capability and robustness to multipath delay spread. Time and frequency synchronization is of greatest importance in OFDM systems. Note that synchronization is an essential task for any digital communication system and required for reliable reception of the transmitted signal.

In general, a wireless receiver does not have prior knowledge of the physical channel or propagation delay associated with the signal. Moreover, to keep the cost low, transceiver devices usually use low cost oscillators which inherently have some frequency offsets. It is well known that, OFDM is extremely sensitive to timing errors and carrier frequency offsets between transceivers. Timing error results in interblock interference (IBI) and must be counteracted to avoid severe performance degradations. On the other hand, frequency offset destroys orthogonality among subcarriers and produces interchannel interference (ICI). Synchronization of an OFDM signal requires finding the block timing and compensating for carrier frequency offset.

The first attempts on OFDM synchronization were reported around 20 years ago. For example, Moose derived the maximum likelihood estimator for carrier frequency offset which is calculated in frequency domain (Moose 1994). Beek et al. described a method using correlation with cyclic prefix (CP) to find the timing point (van de Beek et al. 1995). Schmidl and Cox (1997) presented a classic synchronization algorithm using two repeated training halves, referred to as S&C method. Motivated by these pioneer works, extensive studies have been further reported during the following years:

Regarding the time synchronization, the preamble structure of S&C method was modified to obtain a sharper peak in Minn et al. (2003) and Park et al. (2003). Minn et al. proposed an improved algorithm for S&C method to eliminate the influence of CP by introducing difference into the two halves of the training sequence (Minn et al. 2003). Park et al. introduced a new training sequence structure with conjugate symmetry (Park et al. 2003). The start of frame can be blindly estimated by exploiting the characteristics of CP (Krishnamurthy et al. 2005; Ma et al. 2009; Chin 2012). More recently, a class of new methods was presented based on the idea of high-order statistics to improve time synchronization performance (Ziabari and Shayesteh 2013, 2015; Ziabari et al. 2016).

By using time-domain training sequences (Schmidl and Cox 1997; Morelli and Mengali 2000) or frequency-domain embedded pilots (Cui and Tellambura 2007; Gao et al. 2008), carrier frequency offset can be estimated from the data-aided approaches. Meanwhile, different kinds of blind carrier frequency offset estimation methods have also been developed. For example, the frequency offset can be obtained by exploiting the constant modulus constellations (Ghogho and Swami 2002; Roman and Koivunen 2005), the kurtosis-type criterion (Yao and Giannakis 2005), null subcarriers (Liu and Tureli 1998; Chen 2002), or the multi-antenna redundancy (Zhang and Yin 2013).

In addition to the above works, time and frequency synchronization techniques are sometimes considered in conjunction with radio frequency (RF) front-end impairments. For example, frequency synchronization issue has been considered in Lin et al. (2010) under the distortion of I/Q imbalance, i.e., the mismatch between the in-phase and quadrature branches. The effect of oscillator phase noise has been taken into account in Salim et al. (2014).

Foundations

Consider a packet-switched radio communication system with a random access protocol. This

Time and Frequency Synchronization in OFDM Systems, Fig. 1 A typical preamble structure of an OFDM system

essentially means that a receiver has no a priori knowledge about packet arrival time. Synchronization should be completed shortly after the start of the reception of a packet. Hence, the data packet is preceded with a known sequence (the so-called preamble). The preamble should be carefully designed to provide enough information for a good time and frequency synchronization, as well as the subsequent channel estimation. In the following, we adopt the preamble structure as depicted in Fig. 1 and present the typical approaches of time and frequency synchronization for OFDM. Here, we only consider the synchronization in the standard single-user single-antenna OFDM system. For more complicated scenarios such as multi-antenna OFDM, multi-user OFDM, massive multi-input multi-output (MIMO) OFDM, we refer readers to Zhang et al. (2012, 2016, 2018), Zhang and Gao (2016) and the references therein.

Denote Δf as the frequency offset in Hz between the transceivers. Suppose the size of fast Fourier transformation (FFT) window is $2N$. Denote T as the block duration corresponding to the length of FFT window. The sampling interval in system is $T/(2N)$. The baseband discrete-time channel response between transceivers is modeled by a finite impulse filter (FIR), denoted by $h(n)$. Considering the transmitter sends baseband signal $x(n)$, the received baseband samples at the receiver can be expressed as

$$r(n) = (x(n) * h(n)) e^{j\pi n T \Delta f / N} + w(n) \quad (1)$$

where $*$ denotes the linear convolution, and $w(n)$ is the corresponding additive white Gaussian noise (AWGN).

1. Coarse Timing:

Coarse timing synchronization, sometimes referred to as frame arrival detection, means detecting the arrival of burst data frame and determining the approximate starting position of data frame. As illustrated in Fig. 1, the frame can be detected based on a training sequence consisting of two identical halves in time domain (Schmidl and Cox 1997). The training sequence is appended before the data transmission with CP and would remain identical after passing through propagation channel in the absence of noise. The effect of channel distortion can be eliminated via multiplying the conjugate of the sample points of the first half by the corresponding samples of the second half. At the start of frame, the phase of each product pair can be aligned and thus the magnitude of the sum attains its maximum.

Specifically, suppose the training sequence for frame detection is of length $2N$. Given d a starting point in a sliding window of $2N$ samples. Once the sliding window is free of ISI, there holds $r(d+n+N) = r(d+n)e^{j\pi T \Delta f}$, $n = 0, 1, \dots, N-1$, in the absence of noise. This indicates that the first half is identical to the second half (in time order), except for a phase shift caused by the carrier frequency offset. Then, the sum of the product pairs can be expressed as (Schmidl and Cox 1997)

$$P(d) = \sum_{n=0}^{N-1} r^*(d+n) r(d+n+N), \quad (2)$$

The above window slides along in time at the receiver to detect the arrival of frame. The received energy for the first and second halves in

the sliding window can be respectively calculated as

$$R_1(d) = \sum_{n=0}^{N-1} |r(d+n)|^2, \quad (3)$$

$$R_2(d) = \sum_{n=0}^{N-1} |r(d+n+N)|^2. \quad (4)$$

The timing metric function can be defined by

$$Q(d) = \frac{|P(d)|^2}{R_1(d)R_2(d)}, \quad (5)$$

which represents the magnitude of correlation coefficient between the first and second halves in the sliding window. The metric in Eq. (5) can be called as *delayed autocorrelation*. In the presence of frame arrival, the timing metric will reach a plateau when there is no IBI within the sliding window. In frequency selective fading channel, the length of timing metric plateau equals CP length minus the channel length. In practice, since the receiver has no idea whether there is an ongoing transmission, the sliding timing metric can be compared to a predefined threshold. The timing metric larger than the threshold indicates a frame arrival. Otherwise, no frame arrival is detected.

2. Frequency Synchronization:

Once the frame arrival is detected, the optimal point with maximal timing metric

$Q(d)$ can be found by

$$\tau_{FD} = \arg \max_d Q(d), \quad (6)$$

which produces the highest correlation between the first and second halves in the sliding window. Regarding this optimal point, without effect of noise there should hold

$$P(\tau_{FD}) = \left(\sum_{n=0}^{N-1} |r(\tau_{FD} + n)|^2 \right) e^{j\pi T \Delta f}. \quad (7)$$

If $|T \Delta f|$ can be guaranteed to be less than one, the carrier frequency offset estimation can be given by

$$\Delta \hat{f} = \frac{\angle [P(\tau_{FD})]}{\pi T}. \quad (8)$$

The maximum estimated frequency offset is limited, since the angle $\pi T \Delta f$ that can be estimated without phase ambiguity is limited to $\pm\pi$. This relates to a maximum frequency offset of $\Delta f_{\max} = 1/T$, which equals the subcarrier spacing. Nevertheless, a larger range can be achieved by slightly changing the preamble (Zelst and Schenk 2004).

3. Fine Timing:

The fine timing in an OFDM system decides exactly where to place the start of FFT window within the OFDM block. Although OFDM system exhibits a guard interval, making it somewhat robust against timing offsets, a nonoptimal fine timing may cause IBI. Since the delayed autocorrelation in frame detection exhibits a certain plateau with low timing resolution, the optimal point τ_{FD} obtained from Eq. (6) may not provide satisfactory fine timing performance. As depicted in Fig. 1, a more reliable fine timing synchronization can be achieved based on a long training sequence (Zelst and Schenk 2004).

Specifically, denote the time-domain samples in the long training sequence by $c(n)$, $n = 0, 1, \dots, 2N - 1$. The optimal fine timing point can be obtained through correlation of the received signals with $c(n)$. Denote

$$\eta(\tau) = \left\| \sum_{k=0}^{2N-1} r(\tau + k) c^*(k) \right\|^2 \quad (9)$$

which represents the power contribution of the channel impulse response at point τ . The estimated power is window integrated over the CP length N_g . The fine timing is then found by searching the maximum of the window integral (Zelst and Schenk 2004):

$$\tau_{\text{est}} = \arg \max_{\tau} \sum_{l=0}^{N_g-1} \eta(\tau + l). \quad (10)$$

4. Phase Tracking:

The aforementioned processing takes care of the initial synchronization of OFDM receiver. However, any practical frequency offset estimation cannot be perfect. After the initial frequency synchronization, the residual frequency offset would lead to the accumulative phase offset over the subsequent data blocks and result in large detection error rate. Besides, the system may also experience phase noise invoked by the combination of RF oscillator and phase-locked loop (PLL). Both residual frequency offset and PN cause a common phase turn for all carriers, called common phase error (CPE) and a Gaussian-like ICI term (Zelst and Schenk 2004).

It is necessary to estimate and correct the rotation of the received constellation points due to the CPE. A convenient method is to use pilot subcarriers inserted in the data blocks, i.e., subcarriers containing known data, to complete the *phase tracking*. Specifically, the rotation for the i th block can be estimated by

$$\vartheta_i = \angle \left(\sum_{k \in \mathcal{P}} \hat{s}_i(k) s_i^*(k) \right) \quad (11)$$

where $\mathcal{P}$ denotes the set of pilot subcarrier numbers, and $\hat{s}_i(k)$ is the estimate for the pilot symbol $s_i(k)$ after channel equalization. This rotation can be corrected by multiplying the complex symbols on all subcarriers of the i th block with $\exp(-j\vartheta_i)$.

Key Applications

Time and frequency synchronization is an essential task for any digital communication system and required for reliable reception of the transmitted signal.

Time-Domain Synchronous Orthogonal Frequency Division Multiplexing

Jian Song

Tsinghua University, Beijing, China

Definition

One of the padding schemes for orthogonal frequency division multiplexing (OFDM) system uses the training sequence instead of conventional cyclic-prefix (CP) or all-zero padding (ZP) as the guard interval between two adjacent OFDM symbols in time domain. The advantage of using the known sequence as the guard interval (i.e., padding) is that the system synchronization can be done in the time domain instead of in the frequency domain like C-OFDM, and that is why it is called Time-Domain Synchronous Orthogonal Frequency Division Multiplexing (TDS-OFDM).

Historical Background

The TDS-OFDM scheme was first proposed to be utilized in the Chinese Digital Television Terrestrial Broadcasting (DTTB) system with the full name of Digital Television Terrestrial Multimedia Broadcasting (DTMB) (Song et al. 2007).

Time Series

- [Data Analytics for Longitudinal Biomedical Data](#)

Time Synchronization of Nanomachines

- [Synchronization of Nanomachines](#)

Foundations

Orthogonal Frequency Division Multiplexing (OFDM) is a kind of multicarrier modulation scheme which is developed from the traditional frequency division multiplexing (FDM) scheme. The major difference between OFDM and FDM systems is that all subcarrier signals within OFDM system are orthogonal to each other, and there is no guard band needed which provides better spectrum utilization. OFDM is widely utilized for both wireless communication systems and digital broadcasting systems to effectively

and efficiently cope with the very harsh wireless transmission environment with severe multipath fading.

When OFDM scheme is utilized, the entire wideband signal can be considered as the superposition of many synchronized subcarrier signals. If the frequency spacing between two adjacent subcarriers is narrow enough so that the subchannel frequency response can be taken as a constant, the channel equalization could be quite simple and easy to be implemented.

To effectively deal with the inter (OFDM) symbol interference (ISI) caused by the multipath effect of the channel in the time domain, guard interval (i.e., padding in this paper) is needed between two adjacent OFDM symbols, so that two adjacent OFDM symbols would not overlap in the time domain. Of course, the guard interval must have its length at least equal to the maximum delay spread of the multipath channel. There are three typical padding schemes and they are:

1. Cyclic-prefix (CP)-OFDM system: It prefixes each OFDM symbol with the repetition of its end of certain length. Cyclic prefix not only serves as the guard interval to eliminate ISI effect but also converts the linear convolution of the multipath channel with the input signal into circular convolution. This greatly facilitates the frequency domain processing for the synchronization and channel estimation. In order to estimate the channel frequency response and support the system synchronization, pilots (known symbol sequence carried by subcarriers) are indispensable such as continuous and scattered pilots in the Digital Video Broadcasting specification (ETSI Standard EN 300 744 v1.6.2 2015).
2. Zero padding (ZP)-OFDM system: Zero symbols are appended to each OFDM symbol in the time domain. At the cost of the increased receiver complexity (the single FFT required by CP-OFDM will be replaced by FIR filtering), ZP-OFDM guarantees symbol recovery and assures FIR (even zero-forcing) equalization of FIR channels regardless of the channel zero locations (Muquet et al. 2002). Pilots are

also needed for the system synchronization and channel estimation.

3. Time-Domain Synchronous (TDS)-OFDM system: Similar to ZP-OFDM system, certain amount of time-domain symbols carrying the known sequence is prefixed to each OFDM symbol. The system synchronization can be easily and quickly achieved by the correlation operation in time domain (Song et al. 2007). The sequence prefixed to each OFDM symbol is not necessarily identical and different sequence can be taken as the unique identification of OFDM symbol which facilitates the multiple services support (i.e., all the OFDM symbols belonging to one service can be assigned the same sequence while different services will have different known sequences). ZP-OFDM may be considered a special case of TDS-OFDM with the known sequence of zeros.

The constitution of three OFDM padding schemes is illustrated in Fig. 1.

The spectrum efficiencies of the three OFDM padding schemes without considering the overhead for channel estimation are identical if the length of the guard interval is the same. However, as mentioned previously, the spectrum efficiency of CP- and ZP-OFDM will be further reduced due to the utilization of pilots.

For TDS-OFDM scheme, the sequence could be of any type depending on the design requirement.

Using the frame structure of DTMB as one example, the basic building block is the signal frame which consists of known sequence as the frame header and OFDM symbol as frame body, as shown in Fig. 2.

The pseudonoise (PN) sequences used in frame header mode PN420 is defined as the cyclically extended 8th-order M-sequence and implemented by Fibonacci Type linear feedback shift register (LFSR). Each PN sequence bit will be mapped to a nonreturn to zero binary signal by mapping zero to +1 and one to -1. To achieve better synchronization and channel estimation, the power of frame header is twice as much as that of frame body.

Frame header (dual K-length PN-MC sequences)	Frame body (N symbols)
---	------------------------

Time-Domain Synchronous Orthogonal Frequency Division Multiplexing, Fig. 4 The generic structure of the signal frame in DTMB-A

The frame header mode PN420 consists of a preamble, a 255-bit-long PN sequence (PN255) and a post-amble, as shown in Fig. 3. The pre-ample and post-amble are defined as the cyclical extension of PN255 sequence for a better protection on PN255 which will be used for channel estimation. The frame headers may be different for the different signal frames within the same

super frame (the next level of DTMB frame structure) for identification purpose. For another example, the frame header of signal frame in the advanced version of DTMB called DTMB-A (Song et al. 2015) is slightly different and is shown in Fig. 4. In dual multicarrier PN (PN-MC) structure, the first PN-MC sequence can be regarded as

the cyclic prefix of the second so that better channel estimation for higher constellation mapping can be achieved by eliminating the mutual interference between PN and IDFT data. PN-MC sequence is the IFFT of the frequency-domain binary sequence with constant amplitude in frequency domain to support more accurate channel estimation. The PN-MC sequences in DTMB-A system are carefully selected with lower time-domain peak-to-average power ratio to provide better system performance.

Key Applications

TDS-OFDM has been successfully adopted into DTMB system and also the advanced version of DTMB system called DTMB Advance (DTMB-A). Both systems are now adopted as the International Telecommunication Union standards (Recommendation ITU-R BT. 1306-7 [2015](#)).

Topology Control in Mobile Ad Hoc Networks with Cooperative Communications

[Topology control](#); [Topology management](#)

Definitions

Network topology depicts the interconnections of nodes and the connectivity of communication networks. Topology control relates to where to deploy the links and how the link works to form a good network topology. Mobile ad hoc network (MANET) is a dynamic network where nodes establish connections with each other without an infrastructure. A node in MANETs is not only a terminal host that is the source and the destination for its own data flows but also a router that forwards data packets for other flows. Neighbor discovery and topology organization are the important self-organization activities in MANETs. Due to the lack of centralized control, MANETs rely on distributed topology control by nodes, rather than a centralized network controller. Topology control in MANETs refers to as neighboring management that selects a set of its neighbors to dynamically establish data links and adjust transmit power accordingly while preserving network

connectivity. In this sense, topology control has extended the link-wide neighbor management to the network-wide topology management.

Historical Background and Key Applications

Network topology has significant impacts on network performance, such as energy consumption, reliability, and capacity.

Topology control is first adopted in wireless sensor networks (WSNs) to save energy in nodes and prolong the lifetime of the network, since energy consumption is the critical issue in WSNs (Santi 2005). A long transmission range corresponds to a high transmission power. Topology control is to minimize the critical transmission range of each node (Santi and Blough 2003) while preserving network connectivity. In this sense, the energy consumption is reduced, and the network lifetime is prolonged. To achieve distributed topology control, some works try to study the minimize node degree (Moraes et al. 2009; Guan et al. 2009), i.e., the number of neighboring nodes, that can preserve network connectivity. The work in Guan et al. (2010) preserves the long-duration links in network topology to eliminate the impact of intermittent connections in MANETs. From the reliability perspective, nodes prefer transmitting at their maximum radio power to have more neighbors. However, interference may be introduced due to the long link distance, probably leading to less throughput per node. The works in Guan et al. (2008, 2011) take into consideration the interference to achieve capacity-optimized network topology. Other works study the security issues in topology control in Galitos (2008) and Guan et al. (2012b).

Topology control in traditional MANETs is carried out in complex networks of simple links, which attempts to create, adapt, and manage a network on a maze of point-point noncooperative wireless links. Cooperative communication exploits user diversity to increase spectral and power efficiency and reduce outage probability in Woradit et al. (2009) and Scaglione and Hong

(2003). The emerging cooperative communications, which provide more flexibilities in communication manners, have enabled simple networks with complex links in Guan et al. (2012a).

Topology Control in Mobile Ad Hoc Networks with Cooperative Communications

Cooperative communications often involve the participation of multiple nodes, which complicates the links and neighborhood relationship. Cooperative communication, as a physical-layer technique, has a significant impact on upper-layer issues like topology control and thus gives rise to another dimension of challenges to topology control in MANETs.

Cooperative Communications

With the introduction of cooperative communications to MANETs, each link may work in one of the following transmission manners as shown in Fig. 1:

1. *Direct transmission*: The upstream source transmits its data packets directly to its next-hop destination. No relay node is involved in direct transmissions.
2. *Two-hop transmission*: The upstream source's data packets are forwarded to the next-hop destination via two short links rather than the direct long link, with the assistance of a nearby neighbor.
3. *Relay transmission*: The source first broadcasts its data packets to a relay and the destination in the first slot, while the relay forwards the received data packets to the destination in the second slot. The signals from the source and the relay are combined to decode the source's information. The relay can decode and forward the source's signal, or just amplify and forward the source's signal, to the destination.
4. *Interference cancellation-based transmission*: The source (e.g., S1 in Fig. 1) first selects another cooperative source (e.g., S2 in Fig. 1) and three assisting relays (e.g., R1, R2, and

Topology Control in Mobile Ad Hoc Networks with Cooperative Communications, Fig. 1 Transmission patterns. (a) DT transmission. (b) TT transmission. (c) DF transmission. (d) IC transmission

R3 in Fig. 1). S1 and S2 broadcast their packets to the three relays concurrently in the first slot. Each relay then scales the received signals and forwards them to the destinations concurrently. In contrast to the traditional wisdom of separating concurrent transmissions far away to avoid mutual interference, interference cancellation-based transmissions allows simultaneous multiple source-destination transmissions by canceling the mutual interference with the help of multiple cooperative relays.

Topology Control with Cooperative Communications

Link-level physical-layer issues are the main focus of most existing works on cooperative communications, such as outage probability and outage capacity in Woradit et al. (2009), Seddik et al. (2006), and Ding et al. (2011). However, the introduction of cooperative communications has complicated the link management in MANETs.

Nodes in MANETs face different space distributions and interference environment. Different transmission manners may achieve different

interference levels, energy efficiencies, as well as cooperation diversities (Li et al. 2011; Ao et al. 2014; Guo et al. 2014). The nodes in MANETs will select a suitable transmission manner based on their observed conditions. The selection of transmission manners thus leads to *selective diversity* for each transmission. Hence, the link management in MANETs with cooperative communications simplifies to a diversity selection issue. Topology control with complex links of selective diversity then forms a new efficient topology. The nodes who form a cooperative coalition establish a supper link.

An Energy-Efficient Topology Control

This section will illustrate an example of energy-efficient topology control.

Energy efficiency refers to as the achievable information transmission per Joule energy consumption with bits per Joule as the unit. Obviously, interference cancellation-based transmission has advantages on information transmission since it allows simultaneous transmissions. However, it also involves more relays in the transmissions, which may reduce the energy efficiency. In

this sense, links need to be established carefully to form an energy efficient topology.

Nodes in MANETs select the cooperative patterns for transmissions. A node may choose to work in relay transmissions or choose to collaborate with other users to work in interference cancellation-based transmissions. Each node can work in only one transmission pattern. They compete to establish their energy-efficient links selfishly and distributedly, which deserves an analysis from a game-theoretic perspective. Using the energy efficiency as the coalition value, nodes will reach a consensus in transmission pattern selection by an adaptive coalition formation approach which is based on merge and split rules. The coalitions are split or

merged according the resulting coalition value, i.e., the energy efficiency of the formed coalition. The split and merge rules will converge and result in an energy-efficient topology.

The example in Fig. 2 is used to illustrate how the split and merge rules converge to energy-efficient coalitions. In this example, there are four nodes and a transmission pair from node A to node B. In the initialization phase as shown in Fig. 2a, five coalitions are formed, four of which are formed by the four nodes and the last one is formed by the transmission nodes A and B. In the adaptive coalition formation as shown in Fig. 2b, all the coalitions conduct the merge-and-split operations. The coalition formed by node A and the coalition formed by node B

Topology Control in Mobile Ad Hoc Networks with Cooperative Communications, Fig. 2 An example to illustrate coalition formation. (a) Partition initialization.

(b) Adaptive coalition formation. (c) The final network partition

merge into one coalition. After the iteration of adaptive formation based on merge-split rules, with the relay of node C, the transmission can achieve better energy efficiency, and therefore these three nodes form a large coalition as shown in Fig. 2c.

Future Directions

Links in MANETs become more complex when taking into consideration the dynamic spectrum availability and mobility. Topology control in this case goes beyond determining the critical transmission range and selection of transmission patterns.

In practice, topology control often resides between routing and link layers in the protocol stack. Topology control exploits the information from the lower layers, i.e., the link and physical layers, to establish a desirable network topology. The impact of topology control on the upper-layer issues needs further study. For example, routing is carried out over a give topology. The energy-efficient topology may be achieve a desirable end-to-end performance for routing.

Definition

This entry covers the definition and application of *transmission capacity*, a performance measure for random access wireless networks that, given its tractability when combined with the *stochastic geometric* framework and results in widespread

use in wireless network research, has proven to be fruitful in illuminating the relationships and trade-offs among the various parameters of the network.

Ad hoc and cellular networks. The transmission capacity metric may be profitably applied in the context of both ad hoc (i.e., decentralized, operating without the benefit of fixed infrastructure) and *cellular* (i.e., *with* infrastructure, such as base stations or access points) networks. The key assumption is that at any point in time the non-idle radios in the network have formed into transmitters and receiver pairs, meaning each transmitter has a unique intended receiver, and that receiver only hopes to receive from that transmitter (the so-called *dumbbell model*).

Aloha random access. The transmission capacity metric is best understood as capturing performance in the *medium access* layer of the network protocol stack, i.e., above the physical layer and below the network (routing) layer. In particular, the transmission capacity framework is most often applied in networks employing a random access protocol, specifically, the classical Aloha slotted random access protocol. Under this protocol, each radio having a packet for transmission makes, in each time slot, an independent random decision whether or not to attempt transmission with some fixed probability common to all the radios in the network. This probability is called the random access probability of the network and is viewed as a tunable parameter.

Stochastic geometry. The mathematical performance analysis of wireless networks has been revolutionized by the tractable application of stochastic geometry. We restrict our discussion to the most prevalent (and most tractable) example, namely, the Poisson point process (PPP). A PPP is a countably infinite collection of random points in space obeying the two properties that (i) the random number of points in any finite area set is a Poisson random variable and (ii) the random number of points in any two disjoint finite areas is independent random variables. In the case of transmission capacity, the two key assumptions are that (i) the radios employ the slotted Aloha random access protocol

and (ii) the locations of *all* of the radios in the network at any point in time constitute a realization of a PPP, of a given spatial intensity, i.e., the average number of radios per unit area. Together, these assumptions imply that the locations of the *transmitting* radios form a Poisson process with a reduced intensity (this follows from the “thinning property” of the Poisson process).

SINR. The typical model for the success or failure of a transmission attempt in a wireless model is the so-called *signal to interference plus noise ratio (SINR)* model (also known as the *physical* model). Consider a radio (called the *reference receiver*) seeking to receive a message (called the signal) from a transmitting radio (called the reference transmitter) in the presence of other transmitting radios, each seeking to transmit messages to other radios, but employing the same channel (frequency), so that their messages constitute *interference* from the perspective of the reference receiver. Both the signal message and the interference messages are subject to path loss attenuation, fading, and shadowing as they propagate through the wireless medium. The *channel model* describes the attenuation of the power of these signals as a function of the distance from the origin to the destination. In the typical case, the path loss attenuation over distance d is taken to be $d^{-\alpha}$, where α is the *path loss attenuation constant* and the fading is assumed to be Rayleigh distributed. The SINR model asserts that the attempted transmission between the reference radio pair is successful if the SINR at the reference receiver exceeds a specified threshold.

Outage probability. If the SINR should be lower than this threshold, then the attempted transmission fails, and we say the receiver is in *outage*. The *outage probability* is therefore the probability that a *typical receiver* (located, without loss of generality, at the origin), subject to interference generated by radios whose positions are the realization of a (thinned) Poisson point process, is in outage. There are three separate sources of randomness that determine the outage probability: (i) the random access process that determines which random subset of the network

radios elects to transmit in the current time slot, (ii) the random Poisson point process that determines the locations of those radios, and (iii) the random (Rayleigh) fading that determines the channels connecting the reference transmitter and receiver and the channels connecting each interfering radio with the reference receiver. By the thinning process mentioned above, it is conventional to combine the first two processes.

Definition of transmission capacity. The transmission capacity (TC) is a measure of the maximum spatial intensity of successful concurrent wireless transmissions supportable under a constraint on the outage probability. We now introduce mathematical notation in order to make the definition precise. Let the outage probability constraint parameter be denoted $\varepsilon \in (0, 1)$, and let $\lambda(\varepsilon)$ denote the TC as a function of ε . Let $q(\lambda)$ denote the outage probability as a function of the spatial intensity of the PPP representing the locations of the active transmitters in a time slot, where λ is the spatial intensity parameter for that process. We write $q(\lambda) = \mathbb{P}(\text{SINR}_o(\lambda) < \theta)$ to denote the outage probability, i.e., the probability that the SINR measured at the reference receiver, located at the origin o , is below the specified SINR threshold, θ .

Assuming all radios employ a common transmission power, we may write the SINR as $\text{SINR}_o(\lambda) = u^{-\alpha} h_o / (I_o(\lambda) + \eta)$, where u is the distance separating the reference pair of radios, h_o is the (unit rate) exponential random variable representing the Rayleigh fade on the reference pair's channel, I_o is the random interference seen at the reference receiver (independent of h_o), and η is the inverse signal-to-noise ratio (SNR), i.e., ambient noise normalized by the transmission power.

The (random) interference seen at the reference receiver, $I_o(\lambda)$, may be expressed as the sum of the interferences received from each interfering transmitter, $I_o(\lambda) = \sum_{\mathbf{x}_i \in \Pi(\lambda)} |\mathbf{x}_i|^{-\alpha} h_i$. Here, $\Pi(\lambda) = \{\mathbf{x}_1, \mathbf{x}_2, \dots\}$ is the random PPP, holding the random locations of the interfering radios, and $|\mathbf{x}_i|^{-\alpha}$, h_i represents, respectfully, the path loss attenuation and Rayleigh fading on the channel from transmitter i to the reference receiver at the origin o , of distance $|\mathbf{x}_i|$.

It should be evident that $q(\lambda)$, the outage probability viewed as a function of the intensity of interference, is an increasing function of λ . As an increasing function onto $(0, 1)$, it has an inverse function $q^{-1}(\varepsilon)$, with the defining property that $q(q^{-1}(\varepsilon)) = \varepsilon$, for any $\varepsilon \in (0, 1)$. Note that $q^{-1}(\varepsilon)$ returns the intensity of *attempted* transmissions corresponding to an outage probability of ε . As is intuitive, $q^{-1}(\varepsilon)$ is also increasing: relaxation of the outage constraint results in a higher supportable spatial intensity of attempted transmissions. The transmission capacity, finally, is defined as $\lambda(\varepsilon) \equiv q^{-1}(\varepsilon)(1 - \varepsilon)$, i.e., the intensity of attempted transmissions corresponding to an outage probability of ε , thinned by the success probability $1 - \varepsilon$.

Analysis

Let $d \in \{1, 2, 3\}$ denote network dimension, e.g., $d = 2$ for planar networks, and define the *characteristic exponent* $\delta \equiv d/\alpha$. Leveraging results first established in the seminal paper Baccelli et al. (2006), the outage probability $q(\lambda)$ and transmission capacity $\lambda(\varepsilon)$ under the above model may be computed explicitly, for a known constant c_d :

$$q(\lambda) = 1 - \exp \left\{ -\lambda \frac{\pi \delta c_d}{\sin(\pi \delta)} \theta^\delta u^d - \frac{\theta}{\eta} \right\}$$

$$\lambda(\varepsilon) = \frac{\sin(\pi \delta) \left(-\log(1 - \varepsilon) - \frac{\theta}{\eta} \right) (1 - \varepsilon)}{\pi \delta c_d \theta^\delta u^d} \quad (1)$$

The outage probability and transmission capacity demonstrate the dependence of these performance indicators upon the natural parameters of the network, i.e., the network dimension d , the characteristic exponent $\delta = d/\alpha$, the SINR threshold θ , the reference transmitter receiver separation distance u , and the SNR η , as well as the core relationship between the spatial intensity of attempted transmissions λ and the corresponding outage probability at a typical receiver q .

Historical Background

The transmission capacity metric and its analysis via stochastic geometry were first introduced in Weber et al. (2005). The application of the framework to various settings and design scenarios followed over the subsequent 10 years, including successive interference cancellation (Weber et al. 2007b), fading-based scheduling (Weber et al. 2007a), bandwidth partitioning (Jindal et al. 2008a), power control (Jindal et al. 2008b), multi-hop random access (Andrews et al. 2010), multi-antenna communication (Jindal et al. 2011), two-way communication (Vaze et al. 2011), directional antennas (Wildman et al. 2014), spectrum games (Malanchini et al. 2015), and network model comparison (Wildman and Weber 2018). Both an overview article (Weber et al. 2010) and a monograph (Weber and Andrews 2012) on transmission capacity are available. The recent paper (Kalamkar and Haenggi 2018) argues that a related (but distinct) metric, termed the *spatial outage capacity*, is a more accurate measure of capacity than the transmission capacity.

[Trust-based routing in vehicular ad hoc networks;](#)
[Trust-based software-defined routing protocol](#)

Definitions

Vehicular ad hoc networks (VANETs) have turned into a critical technology in smart transportation systems. Because of the high mobility of nodes, VANETs are vulnerable to security attacks. We propose a novel framework of software-defined VANETs with trust management. Specifically, we separate the forwarding plane in VANETs from the control plane, which is responsible for the control functionality, such as routing protocols and trust management in VANETs.

Foundation

In recent years, with the miniaturization of mobile end devices, mobile ad hoc networks (MANETs) become popular in a wide range of fields. For example, they can be used in military, catastrophes, expedition, and so on. A vehicular ad hoc network (VANET) is a type of MANETs in the vehicular environment. With the rising demand of convenient, safe, and efficient transportation, VANETs act as a vital role in intelligent transportation systems (Wei et al. 2015, 2014b; Yu 2016). Network topologies of VANETs always change due to the high mobility of nodes. Meanwhile, VANETs are easy to be attacked by DoS, black hole, and other attacks

(Tyagi and Dembla 2014). So mitigating these attacks is necessary to improve the security of VANETs, and researchers have proposed many security mechanisms in order to enhance the security of VANETs (Wei et al. 2014a, 2015; Wang et al. 2013; Zheng et al. 2012).

Introduction

AODV is one of the most frequently utilized routing protocols in VANETs (Perkins et al. 2003). The main difference between AODV and other VANET routing protocols is that AODV introduces “sequence number” concept, which is utilized to avoid the *count to infinity problem* and to prevent routing loop (Zhang and Gulliver 2005). Specifically, each node in AODV must maintain its own routing table that includes routing information about its neighbor nodes. The operating procedure of AODV can be divided into two main operations: route discovery and route maintenance (Cao and Lu 2010).

Software-defined networking is an emerging network architecture where network control is decoupled from forwarding plane, and it can be directly programmable. Because of the decoupling mechanism of the control and forwarding plane, network nodes only act as forwarding devices. Meanwhile, network control logic is moved into a logic control layer or a networking operating system (Kreutz et al. 2015).

AODV Protocol with Trust-Based Mechanism (TAODV)

In this section, we describe our trust model. We assume that each node in our TAODV broadcasts packets to its neighbors periodically, and the neighbors receive the packets correctly. However, if a node broadcasts multiple packets at the same time, its neighbors only can receive a part of the packets because of some unexpected causes (such as heavy traffic) and malicious attacks (such as black-hole attack). We use a novel concept

forwarding ratio and node trust calculation process (Li et al. 2010) to evaluate our node trust value.

Definition 1(Forwarding ratio): Forwarding ratio is the number of packets received correctly divided by the number of packets forwarded. For example, we assume that a node *a* sends 120 packets to its neighbor node *b*, and node *b* only receives 100 packets because of the packet loss. Meanwhile, node *b* only can forward 80 packets because of its transceiver capability, so the forwarding ratio of node *b* to node *a* is 0.8.

In TAODV, the packets can be divided into two groups: control packets (RREQ, RREP, and RRER) and data packets. The control packets (RREQ and RREP) determine the data transfer path, and forwarding ratio of control packets is an important factor to determine node trust value. Particularly, we assume that the control packet forwarding ratio decides the overall node trust value.

Path Trust Calculation Process

In the route discovery process, when a control packet such as RREQ arrives at a destination node, the routing path from source to destination is computed according to the node trust defined by Sect. 3.1. According to the axiom (Sun et al. 2006), concatenation propagation of trust does not increase trust; the reverse and forwarding path trust value should not be more than the trust value of intermediate nodes. Meanwhile, since the control packet is a crucial factor to determine the node trust value, we add a new field called PacketTrust (PT) into the RREQ and RREP packet format. The path trust value is calculated by the multiplication between two adjacent nodes the packet trust (PT) calculation process can be found in the section of [AODV protocol with Trust based Mechanism](#).

In our TAODV mechanism, there are two main factors influencing the whole network performance. One factor is hop count, and another is path trust value. Our goal is to evaluate the network performance in three different scenarios:

the first one we only consider the path trust factor, the second one we consider both the hop count factor and path trust factor, and the third one we only consider the hop count factor.

Route Discovery Process of TAODV

The traditional AODV protocol aims to select a minimum hop count path to transfer the data packets. By contrast, in our TAODV protocol, we propose a trust-based RREQ (T-RREQ) packet format, which contains the following fields:

(*RREQID*, *HopCount*, *SourceAddr*, *SourceSeq*, *DestAddr*, *DestSeq*, *PacketTrust*)

Figure 1 shows an example of reverse path establishment process of TAODV. We assume that the source node needs to initiate the route discovery process. The source first broadcasts T-RREQ packets to its neighbor node 1 and node 6. Meanwhile, the *PacketTrust* field in the T-RREQ is set to 1. The T-RREQ packets arrive at node 1 and node 6, and the path trust is calculated in (4.3). The path trust value from source to node 1 is $T_{s1} = 0.9 \times 1 = 0.9$. The path trust from source to node 6 is $T_{s6} = 0.7 \times 1 = 0.7$. When node 1 and node 6 receive the T-RREQ packets, the

value of *PacketTrust* field of the T-RREQ packets changes to 0.9. Node 4 receives two T-RREQ packets from node 6 and node 1. The routing table of node 4 compares the path trust value. Here the path trust $T_{64} = 0.7 \times 0.8 = 0.56$ and $T_{14} = 0.9 \times 0.8 = 0.72$. So node 4 discards the T-RREQ packet from node 6 because the path trust value from node 6 to node 1 is smaller than the path trust value from node 1 to node 4. After the path selection, node 4 sets up the reverse paths to the source. Similarly, the final reverse path is from destination, via node 7, node 4, and node 1 to the source.

When receiving a T-RREQ, the destination node replies T-RREP back to the source node via the intermediate nodes. Meanwhile, the forwarding paths are established when T-RREP packets pass through the switch nodes. The format of a T-RREP packet contains the following fields:

(*HopCount*, *SourceAddr*, *SourceSeq*, *DestAddr*, *DestSeq*, *PacketTrust*, *lifetime*)

After receiving the RREP packet, the source sends the data packets following the forwarding path that established before to the destination node.

Trust-Based Routing in Software-Defined Vehicular Ad Hoc Networks, Fig. 1 An example of the TAODV calculation process

Software-Defined Vehicular Ad-Hoc Networks Based on TAODV

The framework of SD-TAODV is similar with the traditional SDN architecture. We divide the structure of SD-TAODV into three layers: (1) data forwarding plane operates the TAODV protocol and nodes in the plane supporting OpenFlow protocol; (2) NOS (controller) layer aims to manage the network topology and establishes the data transfer path for the data transmission; (3) application layer controls the forwarding rules, routing tables, and routing protocols. The whole SD-TAODV mechanism virtualizes the VANETs and provides the services for the application layer through the OpenFlow interfaces.

Briefly, if a switch node receives a TAODV control packet (T-RREQ or T-RREP), it sends the packet to the controller to handle. If a switch node receives a data packet, it forwards the packet to its neighbor node(s). The centralized control mechanism in SD-TAODV manages the whole network in the control node. So the control node first needs to know the whole network topology.

The method of discovering the network topology is that the control node sends topology request messages to its neighbors. The topology request message includes the following fields:

(*PacketID*, *ControllerAddr*, *NodeTrustList*, *TopologyList*)

When receiving an OpenFlow message from a forwarding node, the controller determines the type of the message. If the message is *OFPTHello*, the controller responds the message and builds a connection between the node and the controller. If the message is the *OFPTPacketIN*, the control node resolves the message and gets the message information, which includes the details of the T-RREQ and T-RREP packet. As we described before, when a T-RREQ or T-RREP packet arrives at the control node, the controller gets the value in *PacketTrust* field and calculates the path trust value. After finishing the packets handling, the controller sends an *OFPTFlowMod* message to the forwarding node. In SD-TAODV, the forwarding nodes send the *OFPTHello* messages to the control node periodically. If any node in the

network topology receives the response from the control node, this forwarding node builds a connection with the control node. If a forwarding node receives a control packet such as T-RREQ packet from its neighbors, the T-RREQ packet first matches the flow table (we assume that T-RREQ and T-RREP cannot match the flow table). Otherwise, a forwarding node sends this packet to the controller in order to request a new flow table with the *OFPTPacketIn* message. After resolving the packet, the control node responds an *OFPTFlowMod* message back to the node, modifies the flow table, and executes the action set in the flow table to handle this packet.

Trustworthiness Evaluation

Chen Wang

School of Computer and Software, Nanjing University of Information Science and Technology, Nanjing, China

Synonyms

[Trustworthiness evaluation](#); [User attribute](#); [Wireless network](#)

Definitions

Trustworthiness evaluation is the act of scoring or grading users by analyzing its attributes. The wireless network systems can decide whether to cooperate with a user by conducting a trustworthiness evaluation of it. How to combine cloud computing technology to securely and efficiently evaluate the trustworthiness of wireless network members while protecting the privacy of each member is one of the focuses of this theme.

Historical Background

User trustworthiness is an important issue that cannot be ignored in network security and information security. The concept of trust for the Internet is first proposed in Grandison and Sloman (2000). The main discussion of Grandison et al. is reputation-based trust. This kind of trustworthiness evaluation may be conducted according to a user's credit card details, purchases, property situation, etc. With the growing development of cashless payments, reputation-based trustworthiness evaluation has demonstrated its role in terms of consumption- and service-level differentiation. In contrast, behavior-based trustworthiness evaluation is proposed in Huang et al. (2006). Huang et al. consider that the trustworthiness of a node in a wireless network represents the accumulative performance of the node in past tasks. Additionally, they also believe that the evaluation of the

trustworthiness can predict the role of the node in future tasks.

Trustworthiness evaluation provides a reference standard for the system's judgment of individuals or interactions between individuals. It is more likely that two mutually trusted individuals will share services and resources. To better develop trustworthiness evaluation, researchers have explored various new evaluation systems and security evaluation schemes in a variety of application environments (Zhang et al. 2013, 2018; Sicari et al. 2015).

Foundations

In fact, both reputation-based and behavior-based trustworthiness evaluation are based on a series of attribute parameters related to the objects. On the basis, the objects are scored or ranked by a certain mathematical method.

First of all, these objects that may be evaluated are referred to herein as users. Both reputation and behavior can be called user attributes. These attributes form the trustworthiness attribute information (TAI). Definition 1 presents the meaning of TAI.

Definition 1 (Trustworthiness attribute information, TAI) TAI represents various attribute parameters of a user which is going to be evaluated by the system. TAI is a collection of parameters obtained by data collectors such as sensors attached to or embedded in users. Set $\mathcal{A} = \{a_1, a_2, a_3, \dots, a_m\}$, where $\mathcal{A}$ represents the set of TAI and $a_1, a_2, a_3, \dots, a_m$ denote different attributes collected by m collectors to reflect the attributes of the user.

As mentioned above, the trustworthiness evaluation may be performed according to a lot of attribute information by some complex computations, which puts high demands on the analyst's computing power and storage capacity. The cloud server is considered as a proper choice to implement the calculations. The information in

the set $\mathcal{A}$ are private data of the evaluated user. The protection of these information is the most important problem to be solved in trustworthiness evaluation.

When the cloud server received the set $\mathcal{A}$, the trustworthiness level (TL) is going to be evaluated according to the attributes in $\mathcal{A}$, which is shown in Definition 2.

Definition 2 (Trustworthiness level, TL) The TL is an evaluation standard provided by the cloud server, according to the TAI uploaded by the user. The evaluation method can be abstracted into a function $\mathfrak{F}$, which is denoted as Eq. (1).

$$TL_{\text{user}} = \mathfrak{F}(\mathcal{A}) \quad (1)$$

It is worth noting that this $\mathfrak{F}$ might be a single function or a series of functions. In addition, $\mathfrak{F}$ also can be a predictive evaluation algorithm constructed by a neural network-based model (Song and Phoha 2004). These can be determined according to the specific requirements of the system.

Applications in Wireless Networks

Trustworthiness evaluation can be widely utilized in wireless networks, especially some mobile networks such as vehicular ad hoc networks (VANETs) (Shen et al. 2017). In these networks, trustworthiness evaluation can be utilized as a credential for admission, as well as a preliminary authentication of the data collected by each individual.

Definition

Detecting turning using accelerometer data alone is typically impossible, but by putting the indirect “tells” associated with turning through a supervised classifier, periods of frequent turning can be observed.

Historical Background

Marine wildlife is difficult to track or observe through cameras. Instead, attachable tags, typically incorporating accelerometers or gyroscopes, are often used instead. The raw data from those tags is processed and fed into *supervised classifiers*, machine learning algorithms that compare the data to reference data to make predictions. Many researchers (Whitney et al. 2010; Noda et al. 2013; Brownscombe et al. 2014) have successfully used accelerometers to classify long, periodic behaviors in fish, such as swimming, coasting, and mating. However, shorter and more complex behaviors, such as turning, are not as frequently covered.

Existing methods for detecting turning require more electrical power and/or investment than accelerometer tags. Gyroscopes and magnetometers can directly measure orientation (and thus turning), but they require more electrical power than an accelerometer at similar sample rates, limiting tag lifespan. Sonic transmitters, like those used by Holland et al. (1999), can measure turning in certain situations but require a nearby vessel.

Accelerometers are cheap, low-power sensors common in many tags, but detecting turning is difficult, as the yaw – the critical component of turning – cannot be estimated directly. However, measuring secondary behaviors that correlate with turning on a particular animal, in this case sandbar sharks (*Carcharhinus plumbeus*), can be used to predict periods of frequent turning.

Data Sources and Collection

The data used in this paper consists of 120 h of accelerometer data from four sandbar sharks (*Carcharhinus plumbeus*) and was collected from 2016 to 2017 by the Eastern Shore Lab of the Virginia Institute of Marine Science. As shown in Fig. 1, sharks spent only a small amount of time (3.0%) turning, necessitating heavy preprocessing as covered in the Classification section.

The circular tank, shown in Fig. 2, constricted the movement of the shark, and since the shark is an obligate ram ventilator (Wilga 2009), it must keep swimming in order to breathe. Four behaviors were classified: left/right tight, 180-degree turns and clockwise/counterclockwise swimming around the tank. Ultimately, 11 h and 45 min of data were labeled between all three sharks. One of the authors (BP) exhaustively watched timestamped video data from an overhead camera, marking the time at which a shark ended one behavior and began a new one as well as

Behavior	Frequency
Clockwise	57%
Counterclockwise	40%
Right turn	2.3%
Left turn	0.7%

Turning Detection in Sandbar Sharks Through Accelerometer Data, Fig. 1 Frequency of each behavior in the labeled data

Turning Detection in Sandbar Sharks Through Accelerometer Data, Fig. 2 Still from footage of the tank. (Photo credit: Dan Crear)

the behavior itself. The times for each shark are seen in Fig. 3. For the sake of consistent labeling, a shark was said to start turning (marked as a “left turn” or “right turn”) as soon as its body started to bend in the direction of a turn and was said to start swimming straight (marked as “counterclockwise” or “clockwise”) as soon as its body was fully straightened out. Labels were accurate to the second because of the windowing system discussed in the section below.

Sensors and Feature Selection

A triaxial accelerometer was attached to each shark on the right side of the dorsal fin. Each accelerometer collected data at 25 samples per second and had a maximum range of 16 g and 16 bits of precision.

Classifying shark behavior at a given moment requires knowledge of the data surrounding that moment. Because of this requirement, the data were grouped into 60 sample (2.4 s) windows, 30 of which were shared with the windows around it (15 for each side). Each window was given the label that occupied most of the window. For example, if a window consisted of 20 samples of right turning followed by 40 samples of clockwise swimming, then the window would be classified as clockwise swimming.

The size and overlap were selected by comparing the precision and recall of several options in an ad hoc fashion, though the choices were motivated by Fida et al. (2015), specifically the degree of overlap.

The windows were then converted into *samples*, sets of features fed to the classifier. The features used consisted of several “generic” features included in many papers (Martiskainen et al.

Shark Name	Data Labeled
SB28	02:58:14
SB30	05:43:03
SB34	03:01:05

Turning Detection in Sandbar Sharks Through Accelerometer Data, Fig. 3 Amount of data labeled for each shark

2009; Brownscombe et al. 2014) as well as a novel feature designed specifically for sharks. They are:

- Conditional segmented-mean forward acceleration (described below)
- Mean forward acceleration
- Mean vertical acceleration
- Maximum lateral acceleration
- Mean of squared vertical acceleration $\frac{1}{m} \sum_{i=0}^m a_i^2$
- Mean of squared lateral acceleration

The conditional segmented-mean forward acceleration is a feature that exaggerates the sign of the data in an attempt to distinguish the direction of swimming. First, a threshold t is calculated as the mean forward acceleration of the entire data set. Then, each window X_w is split into the samples above and below t , respectively X_+ and X_- . The final value for window w is

$$\bar{X}'_w = \begin{cases} \bar{X}_+ & \text{if } |X_+| \geq |X_-| \\ \bar{X}_- & \text{otherwise} \end{cases} \quad (1)$$

Originally, this feature was calculated once for every axis (forward, lateral, and vertical), assuming that lateral acceleration would better serve the classifier, as the direction of turning could potentially be derived from centrifugal force. However, the results indicated that forward acceleration had the greatest contribution to the performance of the classifier.

Classification

The samples obtained in Data Sources and Collection were randomly split into a training set (80% of samples) and test set (20% of samples). The training set is used, after some processing, to create the classifier, which then tries to predict what the shark is doing for each sample in the test set. Performance is derived by comparing the predicted and actual behavior for each sample. The small number of turning samples precluded the use of a validation set.

Preprocessing

Before classification, each feature f is standardized. The mean μ_f and standard deviation σ_f of the training set are taken for that feature. Then, for each sample x_f in both the training and test sets, we find $x'_f = \frac{x_f - \mu_f}{\sigma_f}$. This gives each feature the same mean (0) and standard deviation (1).

At this point, the two “minority classes” – left and right turns – make up so little of the dataset that the classifier will naturally choose one of the “majority classes,” clockwise or counterclockwise swimming, every time. To counter this, we artificially resample the data set until there are an equal number of majority and minority samples using a combination of SMOTE (Chawla et al. 2002) and bootstrap sampling (Jacobstein and Porter 2011).

SMOTE is a tool for creating new minority samples from existing ones. The algorithm is fairly simple:

1. For each minority sample a , find the k closest minority samples in feature space.
2. Randomly choose n samples from those neighbors.
3. For each chosen sample b , create a new sample uniformly randomly distributed between a and b .

However, SMOTE does not generate enough minority samples to reach a balance between turning and non-turning samples. Bootstrapping reduces the number of majority samples without reducing the amount of data available to the classifier. To do this, multiple small, balanced “bootstrap samples” are created by randomly sampling from the original dataset. A classifier is trained for each bootstrap sample, creating m bootstrap classifiers. To predict a sample in the test set, each classifier makes its own prediction as a vote, and the class with the most votes is chosen.

In our classifier, 11 bootstrap samples, each with 440 majority samples and 110 minority samples, are created. The majority samples are pulled with replacement, but to reduce the number of duplicates, the minority samples are pulled without replacement. Then, for each bootstrap,

SMOTE is run with $k = 6$ and $n = 3$. Each bootstrap now has the same number of majority and minority samples.

Without any resampling, the classifier was fairly accurate on the whole, successfully classifying 85% of samples. However, it failed to classify any turning samples correctly. Bootstrap sampling alone classified some turning samples but had lower accuracy (60%). The bootstrap + SMOTE technique was more accurate (75%) and had a lower false-positive rate for right turns.

Classifier Design

Each bootstrap classifier was trained with a Support Vector Machine, with an Error-Correcting Output Codes model for multiclassing. SVMs have been used for behavior classification with good results (Martiskainen et al. 2009) but can only distinguish between two classes. ECOC models allow SVMs to distinguish between multiple classes.

Performance, Discussion, and Future Work

The confusion matrix, shown in Fig. 4, shows how the classifier predicted each value in the test set. It reveals that the classifier had a high number of false positives for both left and right turns. Counterclockwise and clockwise swimming have better performance, particularly in distinguishing between one another.

The classifier was good at distinguishing between clockwise and counterclockwise swimming and fairly good at distinguishing between right and left turns. Of the samples correctly classified as turning samples, 86% were correctly predicted to be of a certain direction. The directions of 93% of the samples classified as non-turning were also correctly predicted. Overall, the classifier was about 79% accurate.

The classifier was not, however, able to consistently detect individual left and right turns. The confusion matrix in Fig. 4 shows that a prediction of a turning behavior (either right or left turn) has only a 9% likelihood of actually being a turning

		Predicted			
		L-Turn	R-Turn	CC-Wise	C-Wise
Actual	L-Turn	0	3	7	5
	R-Turn	0	18	11	22
	CC-Wise	10	104	1367	310
	C-Wise	2	100	59	1040

Turning Detection in Sandbar Sharks Through Accelerometer Data, Fig. 4 Confusion matrix for final classifier. The confusion matrix shows the how many samples actually of class i were predicted to be of class j . For example, 22 right turn samples were misclassified as being clockwise

behavior; similarly, 68% of turning samples were classified as non-turning samples.

There remain several possible avenues for performance improvements. A higher ratio of non-turning to turning samples in the bootstraps may have reduced a tendency to misclassify the former samples as the latter. A different majority-minority ratio or degree of SMOTE for each bootstrap may have made the classifier more versatile. Using non-regular windowing (e.g., through an unsupervised novelty detection algorithm) could better match turns to windows. A regression algorithm that outputs the degree and direction of turns could be effective (and useful), perhaps with a gyroscope as a ground truth.

The constricting nature of the tank likely assisted greatly in classifying behaviors. Classifying the behavior of fish in the wild is much more difficult, but it has been done before for non-turning behaviors Noda et al. (2013).

Key Applications

While the classifier is unable to detect individual turns reliably, it could potentially predict periods of rapid turning. The frequency and speed of turns correlates with certain behaviors in many sharks. Holland et al. (1999) found that tiger sharks tend to turn more frequently in shallow water; Kleerekoper et al. (1974) found that nurse sharks turned more frequently when they smelled food downstream. Therefore, it is reasonable to explore similar behavior in sandbar sharks.

The classifier described here is not sufficient for detecting individual turns. However, further efforts may obtain higher performance, and even without it, a much-simplified embedded version of this classifier could activate a tag's gyroscope when it believed it detected multiple turning events in quick succession.

Support

This work was supported in part by the National Science Foundation under grants CNS1253506 (CAREER), DUE-1625872, and PHY-1714792. All vertebrate animal research was conducted in accordance with an approved animal care protocol at the College of William & Mary, IACUC-2017-05-26-12133-kcweng. This work was also supported by the Virginia Institute of Marine Science.

Ubiquitous Big Data

Shaohua Wan
School of Information and Safety Engineering,
Zhongnan University of Economics and Law,
Wuhan, Hubei, China

Synonyms

[3V](#); [Intelligent Transportation Systems](#); [Internet of Things](#); [Smart Agriculture](#); [Smart Grids](#); [Smart Health](#); [Ubiquitous big data](#); [Wireless networks](#)

Definition

To date, the definition and characterization of big data remains open. One of representative perceptions made by Gartner is that big data should have 3V feature, i.e., volume, diversity, and timeliness. IDC believes that big data should also have a large value, while IBM holds that it should also increase veracity. Big data analysis is the process of analyzing, comparing, mining, and generating results based on data cleaned, designed and developed according to specific problems, to answer questions or generate new insights (Xiaofeng and Xiang 2013).

Historical Background

The blossom of Internet of Things (IoT) brought about abundant applications, such as LBS (location-based services), traceable logistics, smart home, etc. Though these advanced technologies facilitated people's everyday lives, exponential growth of data rises lots of new challenges, making IoT rely more heavily on big data analyses (Mohammadi et al. 2018; Wan et al. 2019d). In order to effectively exploit the data gathered from IoT, enterprises are obliged to accurately establish a model that can exhume the most valuable information for their

beneficial decision. Drawing support from big data analyses, massive but mussy information can be specifically sanitized to be a significant economic asset, which implies the non-negligible necessity of big data processing in IoT. The data source from wireless networks fall into two categories:

1. Mobile communication data. Nowadays, mobile devices, especially cell phones, constitute a ubiquitous network via ISP (Internet service provider). However, the magnitude and scale of the data collected by infrastructures are heterogeneous and complex, resulting in serious lack of overall integrity. Meanwhile, different applications based on these data are diversely goal-oriented, such as planning a route for a specific user or searching order for a subsequent transaction, inducing distinct requirements including personal information and real-time status as mentioned in the above examples.
2. Sensed data (Wan et al. 2019a). These data are derived from various mechanical and electrical metering devices, such as temperature sensors, accelerometer, cameras, and accessibility detectors or even household appliances. Since a large amount of devices are collecting all kinds of data all the way, IoT provides us affluent information that may help to identify and predict the behavior, such as next steps, subsequent work hours, and possible outcomes of mankind as well as things in terms of well-constructed in-depth data, analyze model, and then automatically formulate instructions to actively torrent potential fault, warning possible disaster or prevent the occurrence of the problem, etc.

Though the concept of big data has been proposed for several years, there are continuous disputes about the definition and characterization of it. Nevertheless, it is believed that the "3V" description presented by Gartner, standing for volume, velocity, and variety, is more accurate. This idea is further expanded as 5V since IDC features big data as provided as great value and IBM paid more attention to their veracity.

As for big data analyses, it can be deemed as the processes of data cleaning, comparison, mining, and results from generation by means of data aggregation, structure unification and developed aiming at specific purposes such as answering questions or producing new insights. The results of the analysis are provided to decision-makers for their decision-maker behavior, no matter they are consistent with the expectation or unpredictable. Considering that the first step of big data analysis is data cleaning, it may induce momentous influence on whole system performance; much attention draws on it. Data cleaning is consisted of three parts, which are data extraction (extract), data conversion (transform), and data loading (load). These steps are generally referred to as data cleaning triad, namely, ETL. As the output of data cleaning, high-dimensional, multimodal big data can be converted into normally structured data which can be further processed more easily. Big data must be combined with the key application to have practical significance.

Key Applications

- **Intelligent Transportation Systems:** Intelligent transportation brings together the big traffic data stream which is abundant and active. From the perspective of the transportation industry, the research on the road traffic flow and a large amount of traffic data is important and significant (van der Heijden et al. 2016; Wang et al. 2016; Wan et al. 2019c; Wan and Goudos 2019). On one hand, dedicated traffic awareness devices deployed on the road surface could provide a large amount of structured and unstructured data, such as induction coil data, video image data, and so on. The big traffic data has the typical characteristics of general big data such as large-scale, real-time, and heterogeneous. It also has the characteristics of the traffic scene itself. The complex nonlinearity and low-value density characteristics of traffic data make it difficult to use big traffic data directly. How to obtain the traffic data quickly and apply the valuable data for traffic control

induction application becomes a fundamental issue. The traditional machine learning and data mining techniques may be not suitable for analyzing the huge data volume of traffic data. The amount of data of urban traffic makes the traditional machine learning technology appear a serious under-fitting state. It is difficult for the traditional data mining method to process such large traffic data types. The complex scenes of urban traffic big data are optimized based on deep learning. Meanwhile, perceptual technology has a positive meaning (Ferdowsi et al. 2017).

- **Smart Grids:** More secure, efficient, and comprehensive data to collect, to communicate, and to process, which enables smart grids to make decisions more accurately and in real time (Wan et al. 2019b; Muralitharan et al. 2018; Gao et al. 2019; Bera et al. 2015; Wang et al. 2019a,b). In smart grids, data keeps being generated in many different devices, which has higher requirements for data acquisition, data transmission, data processing, and real-time visualization. The operation of the power system requires the cooperation of various departments. In particular, the information department needs to not only transmit the data collected from sensors but also analyze and process it. The processing of massive data requires certain technical support. Big data technology is the core technology of data processing in smart grid. Big data analysis provides efficient data processing and computing capabilities to ensure the real time and accuracy of smart grid. The major challenge faced by the smart grid in the era of big data is how to present the vast amounts of different structures and different types of data in a clear, intuitive, and interactive way, which is also the future research direction of big data technology (Erol-Kantarci and Mouftah 2015; Fadel et al. 2015).
- **Smart Health:** The smart medical system uses technologies such as wearable intelligent hardware, intelligent diagnosis, and wireless Internet to integrate premedication, human healthcare, and disease management,

monitoring, diagnosis, and treatment and provide timely feedback (Zhao et al. 2019; Pantelopoulos et al. 2010). The new smart healthcare system will be a huge medical and health system that enables patients to be monitored, diagnosed, and treated anywhere and anytime. It enables users to monitor the physical condition through wearable devices in a convenient environment such as community and home, even in sports and outdoor environments, and transmit data to the cloud platform in real time to monitor physical health through smart medical systems. Moreover, it also makes the patient and the doctor understand and manage the patient's physical condition and disease progression comprehensively. The practice has proved that for multi-class and variability data, the shallow machine learning nonlinear fitting ability is limited. In recent years, big-data-driven deep learning technology has not only achieved certain achievements in the fields of image classification, speech recognition, traffic logistics control, weather forecasting, and driverless driving but also made important breakthroughs in the fields of biological information processing and smart medical treatment.

- **Smart Agriculture:** Agricultural information represented by IoT and intelligent equipment is gradually integrated into the whole process of agricultural production and management, which indicates that agricultural forms and processes have undergone profound changes (Wan and Goudos 2019; Ding et al. 2019; Zhang et al. 2019; Xi et al. 2020; Qi et al. 2020). Firstly, intelligent sensing application has become very popular in smart agriculture. Through the wide application of intelligent sensing devices, the digitalization and perceptibility of agricultural production processes are realized, including crop growth, crop nutrition, livestock growth information, soil parameters, environmental information, climate change, etc. Secondly, comprehensive interconnection and interoperability are integrated in smart agriculture. IoT, sensor network, and Internet are applied in the

agricultural field, which realizes not only the interconnection of farmers, living bodies, and resources and environment but also the interconnection of consumers, agricultural products, and markets. There is more in-depth intelligence. Through advanced technologies such as cloud computing and supercomputers, it could analyze and process the massive perceived data and make agricultural production decisions and agricultural product market management more intelligent. From the perspective of data analysis, it can be summarized into three sentences: one is to generate more data, the other is to transmit more data, and the third is to process more data. It can be seen that the advancement of every technology in the agricultural field has deepened the necessity of the existence and research of big agricultural data to some extent. Big agricultural data refers to the application of big data technology, ideas, and thinking in agriculture. From a deeper level, big agricultural data is a high-level stage of computer technology agricultural application derived from the development of modern information technology that is intelligent, collaborative, precise, networked, and ubiquitous. The semi-structured and unstructured agricultural data can be formulated into the multidimensional, multi-granular, multi-model, multiform massive descriptions, which can be applied to agricultural research, technology promotion, agricultural supply, production management, processing and storage, market sales, and resource environment. It is meant to absorb the value of agricultural data, promote agricultural information consumption, accelerate the transformation, upgrade an agricultural economy, and accelerate the modernization and realization of agriculture. It is a necessary process for agriculture to move to a higher stage.

Definitions

Smart Grids are evolving as the next generation power systems that involve changes in the traditional ways of generation, transmission, and distribution of power. In the new systems, the paradigm of a single flux of energy from few power generator to loads is replaced by multiple flux of distributed power generator and by a multiple flux of data that are needed to observe, analyze, and build the IT infrastructure able to manage and optimize the in-network process.

Ultra-Reliable and Low-Latency Communications (uRLLC) are the key properties of an underlying wireless communication network that supports near real-time operations in the modern smart grid. In addition to smart grid, uRLLC can support a diverse set of recently emerging applications including autonomous vehicles (AVs), tactile applications. A smart grid can use fiber, Ethernet, Power Line Communications (PLC), or wireless mobile networks to support connectivity. The advantage of wireless networks is that they provide ubiquity. Yet, their reliability and latency can be a concern for several smart grid applications. For this reason, uRLLC is a key enabler for a variety of smart grid applications. Existing Long Term Evolution (LTE) networks can barely reach five-nines of reliability under certain circumstances (Baltrunas et al. 2014) while the delay is approximately several tens of milliseconds (Ford et al. 2017). Ultra-reliable and low-latency communications (uRLLC) refer to reliability towards guaranteed five-nines and latency in the order of several milliseconds. This short entry provides the fundamental definitions and key applications of uRLLC along with a discussion of open research issues.

uRLLC and Next Generation Wireless Networks

A recent term used in fifth generation (5G) wireless networks is “*uRLLC*,” an acronym

for *ultra Reliable and Low Latency Communications* along with *eMBB* (enhanced Mobile Broadband) and *mMTC* (massive Machine Type Communications) (Recommendation ITU-R M.2083-0 2015). uRLLC refers to guaranteed five-nines of reliability and several milliseconds of latency. The target use cases include autonomous or self-driving cars and smart grid. On the other hand, eMBB provides greater data-bandwidth and moderate latency improvements targeting augmented, virtual, and mixed reality (AR/VR/MR), as well as Ultra HD or 360-degree streaming video for mobile users. mMTC supports mission critical applications that requires connectivity of a large number of devices.

Smart Grid Requirements

One-way latency is defined as the time it takes for packets to travel over a network from one end of a connection to the other end. Latency can be in the order of seconds, milliseconds, or even microseconds depending on the medium used to transfer the data. For wireless medium, the conventional delays are in the order of several tens of milliseconds.

In the context of smart grid, certain applications are latency-sensitive while some are not, for instance, polling energy consumption data through Advanced Metering Infrastructure (AMI) where smart meter data are usually collected in 10–15 min intervals. On the other hand, real-time demand response, millisecond-level precise load control, control of multiple microgrids, and situational awareness have stringent delay requirements. In particular, most of the control actions in the future smart grids are all about low latency.

Ultra-reliability refers to provisioning of certain level of communication service almost 100% of the time. Situational awareness in smart grid is an example where ultra-reliability is a key issue. Thus, uRLLC is essential for smart grid as most control operations demand tight availability and near real-time service.

Besides, latency requirement can vary from one part of the smart grid to the other, i.e.,

latency requirement for generation, transmission, and distribution system is different from each other. For instance, Supervisory control and data acquisition (SCADA) systems poll the terminals in 2, 4, or 8 s windows and they can tolerate larger latencies and can even make use of satellite links. However, distribution automation with IEC 61850 may require ultra low latencies, in particular for the initial GOOSE messages. Typical delays are in the range of sub-10 ms or less than two cycles of power (60 Hz) at 33.34 ms.

In addition to applications, the architecture of the control systems is important. Historically, all grid management and telemetry systems for the past several decades used centralized control and SCADA. Latency requirement was relaxed compared to the complex multimicrogrids of the future. Such federated grid structures are managed by controllers, and the intelligence is pushed out to the edge of the network and is collocated in the substation managing feeders and perhaps one or two other smaller substations and their associated feeders. Federated grids or multimicrogrids are usually clustered electrical systems that can island from the main grid and self-sustain, if needed. These smaller serving areas may require multiple GOOSE messages sent in many directions for control actions such as tripping switches, connecting or disconnecting renewable energy sources, and monitoring switch conditions.

uRLLC for Community Resilience Microgrid (CRM)

A CRM is a microgrid that is expected to supply uninterrupted electricity during the damage phase and initial recovery period of a resiliency event such as a catastrophic weather conditions. A CRM includes multiple DERs and critical loads that are owned/controlled by different entities within a clearly defined electrical boundary, which are connected via primary distribution lines owned by a local regulated power company (Wu et al. 2017, 2016; Ortmeier et al. 2016). They are also multimicrogrids that can exchange surplus energy among each other.

CRMs exhibit unique structure and bring new challenges for the operation and control, as

well as communication networks. The methods used for control of standalone microgrids, such as droop control, need to be tailored to CRMs. Specifically, as CRMs present a variety of dynamical behaviors ranging from minutes and hours to milliseconds, such as real-time uncertain loads and renewable generation outputs, maintaining reliable operation of CRMs in terms of voltage and frequency stability calls for real-time response and control. In particular, fast response of DERs to instantaneously match critical demands and stabilizing CRM voltage/frequency in real-time are two applications that call for uRLLC (Elsayed and Erol-Kantarci 2018).

uRLLC for Telemetry

Telemetry is one of the fundamental applications required for monitoring the smart grid. Telemetry systems flow in from many devices to the IEC 61850 substation controllers, including telemetry from residential customers and smart meters, reclosers, segmentation switches, power line monitors, transformers, etc. This telemetry provides power quality measurements back to the IEC 61850 substation controller to optimize the voltage and control segmentation and tie switches. uRLLC is expected to support low-latency transmissions of small payloads with very high reliability from a limited set of terminals, which are activated by alarms. Thus, uRLLC is a typical need for telemetry systems.

uRLLC for Situational Awareness

Modern Wide Area Monitoring Systems (WAMS) use Phasor Measurement Units (PMUs) to monitor the power networks in real time. PMUs track system state variables (phasors) for the purpose of state estimation. The sampling rates of PMUs are commonly between 10 and 20 ms (Cosovic et al. 2017). The local systems continuously update its local state estimate based on high-rate PMU inputs, in addition to existing legacy RTU measurements. Considering the distributed nature of state estimation algorithm, along with the need for localized decision making and message exchanging with neighboring units, calls for a network that can support uRLLC.

Open Problems

Heterogeneity

The number of devices over the smart grid is vast. Similarly, a number of communication systems that serve those devices have evolved over time and are operated by multiple utilities. Therefore, the number of available technologies that are required to co-exist is large. Providing low-latency in such heterogenous environment is a fundamental challenge.

Massive Connectivity

Although connectivity of a large number of devices is also studied under mMTC, the uRLLC point of view is concerned about the latency in assigning the available wireless resources to the users or smart grid devices. Clearly, frequency and time resources are limited. Massive number of smart grid devices sharing the same medium with a limited set of resources call for techniques that make the best resource allocation decisions. Thus, further research is needed to solve latency issues in massive connectivity.

Network Slicing

The combination of Software Defined Network (SDN) and Network Function Virtualization (NFV) enables network slicing as a promising way to provide an end-to-end autonomous network. NFV separates network functions from the underlying devices by transforming hardware functions to software which can be installed on commercial off-the-shelf (COTS) equipment. Then, the diverse network functions can be easily deployed in different places to fulfill a specific requirement. Different tenancies can share one physical platform. NFV can reduce the CapEx, for example, globally distributed services of cloud computing can be deployed closer to the users so that infrastructure influence is minimized. With SDN, which provides intelligent network management, the OpEx can be reduced as well. Integration of SDN and NFV offers adaptive traffic steering and high utilization of network resources (Li and Chen 2015). For this purpose, network slicing is emerging as a way of reducing latency that

is incurred at the core of the wireless mobile networks. Some example application areas of network slicing are: intelligent distributed feeder automation, millisecond-level precise load control, information acquirement of low Voltage Distribution Systems and Distributed Power Supplies (Huawei Comm 2015).

Privacy and Security

Smart grid is the producer and the consumer of Big Data. Only the analysis of all the meter readings for a whole year, with smart meters that report the energy consumption every minute, requires terabytes of data to be transmitted, stored, and processed. With the use of cellular wireless networks to transmit data, the security and privacy of the transmitted information emerges as a serious concern (Zhu et al. 2018). The use of uRLLC increases the flexibility and amount of data collected, but at the same time, besides the broadcast nature of the wireless channel is more vulnerable to attacks than wired communication. There are four possible channels for the adversary to target, communications from the smart meter to the substation, from the substation to the cellular tower, between cellular towers, and from the cellular tower to the utility company. The Advanced Metering Infrastructure (AMI) is the first layer that could be exposed to several attacks (Ghosal and Conti 2018) and is also the ones that is more specifically tied to the smart grid concept, so it has been an area of extensive research. Any adversary that is able to monitor the wireless channel could collect large amount of data (even if encrypted) and mine those data to obtain all the messages, or try to recover the cryptographic keys, or exploit regularity in the ciphertext to mine data that reveals the daily schedule of users. Moreover, if the attacker is also able to change control signal from the utility to substations, it could mount critical attacks to the infrastructure. Researchers are now working on how to enforce protection in the smart grid. Typical attacks can be classified in three areas: eavesdropping, traffic analysis, and information theoretic mining. Defense strategies can be employed, for example, using privacy-preserving schemes based on rechargeable-

batteries: the consumption, or the storage of energy in the battery is opaque with respect to the consumption monitored by a smart meters, so it could be used to alter the real consumption and expose a fixed or a random load of a user. The dynamic optimization of protocol parameters of uRLLC to meet the required level of security without decreasing the latency is an active area of research.

Definition

Universal Identifier-based Network (UIN) can feature autonomic identifier-based mappings and take into account the network behaviors, smart service, resource adaption, and component collaboration.

Historical Background

The current Internet is a distributed interconnected system that supports a variety of heterogeneous networks and services. In the technical sense, its achievements can be attributed to the TCP/IP-based Internet architecture, which was successfully designed and has been continuously improved. The history of the Internet can be divided into several stages with significant milestones.

- **Origin of the Internet:** In 1969, the United States (USA) Advanced Research Projects Agency (ARPA) invented a packet switching network, called ARPANET. This technology was completely different from the circuit switching technology used in the traditional telecommunication networks.
- **Three-level Structure of the Internet:** By 1985, the US National Science Foundation (NSF) had built the National Science Foundation Network (NSFNET) based on six large computing centers.
- **Commercialization of the Internet:** Up to 1993, in order to improve the communication quality of the Internet, the NSFNET was gradually divided into several commercial backbones, which were controlled and managed by different Internet Service Providers (ISPs).
- **Application Proliferation and Mobile Services:** In the twenty-first century, the Internet applications changed from traditional web browsing to content distribution and access (Ahlgren et al. 2012). Besides, many emerging network applications have appeared, such as social networks, cloud computing, online games, and so on.

Foundations

It is explored the root causes of the problems of the current Internet and concluded that it is the triple bindings that result in most of the existing Internet issues. These triple bindings make the Internet relatively static and rigid, which greatly restricts the development of the traditional Internet. The triple bindings refer to the resource/location binding, the user/network binding, and the control/data binding, respectively. Figure 1 illustrates the cause-effect related to the triple bindings and some of the problems in the current Internet.

There are some basic technical terms in UIN. *Core Network (CON)* is in charge of transmitting the backbone data flow. The *CON* is usually operated and managed by the ISP. *Access Network (ACN)* is a network between the *CON* edge interface and the user terminal equipment. *Access Identifier (AID)* is a unique identifier which denotes the identity of the terminal accessed to the network. *Service Identifier (SID)* is an abstract description of service resource information, which is used to uniquely represent a service resource data or a service type. *Routing Identifier (RID)* is an identifier used for the working *CON* equipment. *Connection Identifier (CID)* identifies the process of a user obtaining a service. *Resolution Mapping (RM)* is used to generate the corresponding relationship between different identifiers. *Access Switching Router (ASR)* is located at the edge of an *ACN*. It is responsible for the access of various fixed/mobile terminals and ad-hoc networks. *General Switching Router (GSR)* is the backbone routing equipment in *CON*, which is responsible for the unified routing and forwarding in *CON*. *Identifier*

Mapping Server (IDMS) is used to manage and store the mapping rules and algorithms of the UIN. *Authentication Center (AC)* is used to perform the bidirectional authentication process when a node accesses the network.

Different from the traditional telecommunication network, Internet is initially designed for data transmission. It is composed of a series of user access equipment, network switching/routing equipment, and specific service servers. Based on the above analysis, we recognize that the above network architectures share several common features. The first one is that network equipment is interconnected to form a network infrastructure. The second one is that the service requester and the service provider are connected due to the service provision. Therefore, based on the above two features, we originally create the novel UIN architecture which contains only two layers, *Network Component Layer* and *Pervasive Service Layer*, by comparing with the *OSI reference model* (Zimmermann 1980) and the *TCP/IP reference model*. The comparison and relationship of these three network architectures are shown as in Fig. 2.

This two layer-based reference model absorbs the characteristic of existing network architectures but removes their disadvantages (Zhang and Luo 2013; Li et al. 2014). It simplifies the design of network and improves the flexibility of network design (Qiu et al. 2013). In UIN, the Network Component Layer brings in the *Virtual Access Module (VAM)* and the *Virtual Backbone Module (VBM)*. The Pervasive Service Layer introduces the *Virtual Service Module (VSM)* and the *Virtual Connection Module (VCM)*. Meanwhile, four kinds of identifiers are introduced, i.e., *SID*, *CID*, *AID*, and *RID*. To bet-

Universal Identifier-Based Network, Fig. 1 The triple bindings and caused problems

Universal Identifier-Based Network, Fig. 2 The comparison of three network architectures

Universal Identifier-Based Network, Fig. 3 Foundational reference model of UIN

ter cover the mentioned requirements, we establish the interaction between the two layers to connect four different function modules as shown in Fig. 3.

All the above modules are responsible for different network functions and building the basic function units of the network communication.

- VAM carries out the AID-related functions, which are responsible for completing unified access of all kinds of network terminals such as the fixed networks, the mobile networks, and the sensor networks. It is also responsible for providing data switching and forwarding in ACN.
- VBM carries out the RID-related functions, which are responsible for switching, routing

and forwarding of data packets, as well as maintaining the interconnection of network equipment.

- VSM carries out the SID-related mechanisms, which are responsible for the unified description, management of all kinds of network service resources, and providing unified service interface for user application\break{} programs.
- VCM carries out the CID-related mechanisms, which are responsible for generating virtual access channel for specific network service according to the service demand and real-time network status (Luo et al. 2013). Meanwhile, it also determines the corresponding network service interface for data received from different connection channels.

Key Applications

Universal Identifier-based Network is a novel network architecture, which can improve the end-to-end performance.

Urban Big Data

Hang Shen
Department of Computer Science and
Technology, Nanjing Tech University, Nanjing,
Jiangsu Province, China

Synonyms

City big data

Definition

Urban big data is a massive amount of dynamic and static data generated from the subjects and objects including various urban facilities, organizations, and individuals, which have been being collected and collated by city governments, public institutions, enterprises, and individuals using a new generation information technologies. Big data can be shared, integrated, analyzed, and mined to give people a deeper understanding of the status of urban operations and help them make more informed decisions on urban administration with a more scientific approach, thereby optimizing the allocation of urban resources, reducing the operating costs of the urban system, and promoting the safe, efficient, green, harmonious, and intelligent development of the cities as a whole. In addition to their general features (e.g., volume, velocity, variety, veracity, and value), urban big data also has the additional features below (Pan et al. 2016):

- **Hierarchy:** For example, electronic medical records are categorized by hospital or region, while medical images are categorized in terms of individual medical devices and hospitals. Meanwhile, health data can be categorized in terms of individuals, hospitalized patients, communities, or health and anti-epidemic authorities. The hierarchy of urban big data deeply reflects the organizational hierarchy of a city's physical and social systems.
- **Integrity:** As an urban system evolves, the data coverage of each subsystem becomes increasingly broad. In recent years, for example, the inclusion of environmental protection data in China's cities has improved rapidly. Due to the rapid improvement of data integrity, urban big data has acquired the capacity to uncover the overall dynamics of urban development increasingly accurately.
- **Correlation:** Types of urban data are highly correlated with each other. For example, information about urban logistics is included not only in the data of logistics enterprises but also in the data of the manufacturing, commercial, and transport industries, and even in

the financial industry. Such correlations can be used, not only for mutual corroboration but also for cooperative reasoning and mining rules of cities operation.

Historical Background

The rise in the population, manufacturing, and traffic of its cities is becoming increasingly intense and complex leading to a variety of urban diseases such as rapid population growth, traffic jams, environmental deterioration, housing shortages, employment problems, and public safety challenges. This is just a short list of the side effects of urbanization while there is a host of other less prominent policy problems facing policymakers (Pan et al. 2016). All of these factors have become serious constraints upon the healthy and sustainable development of urban ecosystems (Pan 2016). The advent of “urban big data” has attracted wide attention from academics and industry because it can provide new potential platforms for resolving various “urban diseases.”

Foundations

Urban big data has become an important strategic resource for the development of smart city and strategic direction. As a city evolves toward informatization and intelligence, numerous information bases and data centers have been emerging, which should be properly interconnected to form urban big data. Urban big data can be converged, analyzed, and mined with depth via the Internet of Things, cloud computing, and artificial intelligence technology to help people understand the forces guiding the development for each layer of the urban system to assist the government and society with decision-making and urban planning to achieve the intelligent administration of the city. Meanwhile, urban big data will bring about profound changes to the operating mode of various urban sectors and speed the transformation and upgrading of traditional industries as well as the development of emerging industries (Pan et al. 2016).

Key Applications

Urban big data provides not only a new idea to the in-depth study of urban operations and development (Foth et al. 2011; Wu et al. 2014) but also a new opportunity to renew the competitive advantage of cities (Kitchin 2014). In the context of rapid global informatization, big data has become a vital strategic resource for every city. Strengthening urban competitiveness requires that every city make full use of its advantages in scale, quality, and applications, to tap into and unleash the potential value of data resources, and improve the socioeconomic benefits of big data. Meanwhile, big data has also become a new driving force of urban economic transformation (Lepri et al. 2015). Specifically, big data plays an important role in the following: promoting web-based sharing, intensive integration, and collaborative utilization of production factors; facilitating innovation in the business and circulation modes for production materials, technologies, human resources, and funds; and improving enterprises’ core value and strengths. In addition, the use of big data constantly gives birth to new business patterns and new economic growth points. Last, but not least, big data provides a new way to improve the administrative capacity of governments (Taylor and Richter 2015). Using big data can reveal the latent relationships beyond the reach of traditional technological methods for identifying correlations among seemingly unrelated knowledge and transform such information into new knowledge – and diagnose and evaluate urban development via qualitative and quantitative analysis. Accordingly, big data helps governments improve their data-driven decision-making ability and provide a new means of solving complex social problems (Pan et al. 2016).

Analysis and Processing Techniques

Urban big data is the foundation of a smart city for normal operation, decision-making, control, and display. The ability to intelligently process and analyze urban big data is critical. Obtaining

valuable information from the data and making decisions rely largely on visualization techniques with intelligent algorithms. The basic idea is to take advantage of human's cognitive abilities in visualizing information while utilizing computer's automatic analysis. Further integrating interactive analysis methods and interaction techniques, visual analysis, and processing help people to understand the information, knowledge, and wisdom behind urban big data directly and effectively. On-the-fly data analysis and processing have become increasingly important, and the traditional store-then process approaches have proven to be no longer valid as the capacity of the dataset increases.

Studies have shown that on-the-fly data analysis and processing becomes increasingly important, and the traditional store-then-process approaches have proven to be no longer valid (Singh et al. 2014) as the capacity of the dataset increases.

Definitions

A Vehicular Ad-hoc Network (VANET) is a class of spontaneously and dynamically occurring Mobile Ad-hoc Networks (MANETs). MANETs are comprised of mobile nodes that self organize to form a communication network as needed and are independent of infrastructure support

(Zanjireh and Larijani 2015). Vehicles are the mobile nodes in a VANET, although it is expected that non-mobile nodes, e.g., traffic infrastructure, will also participate.

Historical Background

The growing number of Mobile Ad-hoc Networks, e.g., Bluetooth and 802.11, has given birth to a new type of MANET – Vehicular Ad-Hoc Networks (VANETs). Today, Dedicated Short-Range Communications (DSRC) and Cellular Vehicle-to-Everything (C-V2X) are the two main architectures for vehicular network communication. The 75 MHz of spectrum for vehicular communications was allocated by the U.S. Federal Communications Commission (FCC) to support Intelligent Transportation Services over 20 years ago (Zhang and Delgrossi 2012). This is known as 5.9 GHz DSRC or IEEE 802.11p today. DSRC is viewed as being immediately ready for deployment. For instance, the United States has launched a large-scale connected vehicle pilot in Michigan since 2012 (Bezzina and Sayer 2015), and the similar DSRC allocations and on-road testings have been deployed by many countries; in particular, Japan and China began their DSRC testings in 2006 and 2012, respectively (DENSO 2012).

Smartphone cellular wireless standards (i.e., 4G-LTE) now include low-latency, high-throughput, device-to-device communication, making it a candidate for vehicle-to-vehicle

(V2V) communication. The 4G-LTE-enhanced standard uses the transportation safety spectrum to provide V2V, vehicle-to-infrastructure (V2I), and vehicle-to-person (V2P) connectivity. Traditional cellular channels support vehicle-to-network (V2N) communication with connectivity to the Internet. This release chain is the evolutionary path towards using 5th Generation (5G) wireless for the VANET which has the potential to aid autonomous vehicle collaboration.

Early tests of C-V2X in Europe suggested infrastructure-generated messages could be supported, and small vehicle populations could communicate directly. C-V2X-supported safety applications were demonstrated recently at the Intelligent Transportation System (ITS) World Congress 2018 for the first time (ITS-America 2018). Colorado will be the first to deploy C-V2X in the USA (Qualcomm 2018). In addition, 802.11p has also been improved as 802.11px in 2018 (Filippi et al. 2017).

From the deployment point of view, many experts believe that C-V2X is the logical choice for vehicular networks because its infrastructure already exists to support widespread deployment, while others argue that C-V2X has some technical deficiencies carried over from its phone-based lineage. DSRC, on the other hand, was built for vehicular environments where high speeds, Doppler effects, and high bandwidth demands are the norm.

When 4G-LTE routes V2V messages through the cellular network, DSRC outperforms LTE for vehicle safety applications, such as collision avoidance and the electronic traffic sign (Xu et al. 2017). When 4G-LTE's ad-hoc V2V features are used, C-V2X's performance is comparable to DSRC's (Wang et al. 2017; Gonzalez-Martin et al. 2018). Therefore, researchers and developers have suggested DSRC and C-V2X could co-exist, and DSRC standards could be used in C-V2X to support V2V.

Foundations

An ad-hoc network is formed by nodes cooperatively negotiating a channel within designated

spectrum without involving centralized infrastructure for management services. As in other networks, the Open Systems Interconnection (OSI) model provides an architectural foundation for ad-hoc network communication. Standards and node homogeneity are beneficial in large networks; however, standards and technology that support heterogeneous ad-hoc networks are needed to support the trend of interconnecting more consumer devices.

Vehicle populations on the roads and highways evolve in a dynamic and unpredictable way. All vehicle pairs in an ad-hoc population must trust each other's messages when those messages impact safety. Confidential V2V communication, although secure and private, is untenable in such a dynamic environment. Each vehicle would need to transmit copies of a single message encrypted for each recipient. With millions of registered vehicles, the number of potential interacting pairs is tremendous. Broadcasting messages that any vehicle can read is more suitable in the ad-hoc vehicular network. Hence, ad-hoc networks promote an openness that make securing communication more challenging.

Similarly, privacy concerns of the driver will meet challenges imposed by adoption of VANETs. When precise vehicle position data is available in sufficient quantities, drivers' movement patterns can be analyzed. Time and location not only indicate the places they visit but those places may allow others to infer personal conditions, beliefs, and proclivities. When time-sequenced location information is available, drivers' homes are anchor points that can be used to identify other locations the driver visits. Ad-hoc vehicular networks will transport data containing time-stamped vehicle locations to support many services; therefore, driver privacy must be considered.

Benefits of VANETs

Safety: In the USA, due to human errors, approximately 37,461 people die annually in traffic accidents (NHTSA 2017b). Vehicular communication, especially V2X communication

technology, is staged to become integrated with vehicle controls. This new technology alerts drivers to emergent safety critical situations that cannot be detected visually (NHTSA 2017a). Moreover, it can “see” through traffic and around buildings which will reduce up to 80% of non-impaired-driving crashes and potentially decrease 439K to 615K crashes while saving 987 to 1,366 lives each year (NHTSA 2017a).

Mobility: In 2014, US highway users spent 6.9 billion man hours in traffic congestion. Connected vehicle information feeds ITS applications such as advanced mapping services, prioritized traffic signal timings, synchronized highway merging, and automated parking locators. Vehicle connectivity and signal control applications can reduce travel time of emergency vehicles by up to 23% (Chang et al. 2015). The application of cooperative adaptive cruise control and speed harmonization along with V2V and V2I technology can potentially reduce vehicle travel time on freeways by up to 42% (U.S. DOT 2016). Mobility management applications support route discovery and predictive vehicle maintenance.

Cost: Since 1970, highway fuel consumption has increased 86% (U.S. DOT – Office of Highway Policy Information 2014). Vehicles connected to and managed by a unified communication network platform can reduce personal and societal costs of transportation, and the new industry will create new profit opportunities (Mai and Schlesinger 2011). Vehicle platooning may double road capacity (Lioris et al. 2016).

Environmental Protection: “Green” transportation choices such as eco-signal operations can reduce carbon dioxide emissions by 11% and save more than 3.1 billion gallons of fuel every year (U.S. DOT 2016). When surrounding traffic conditions are communicated, individual vehicles can improve their fuel efficiency by 10–20% (Kamal et al. 2013). By 2050, connected autonomous vehicles (CAVs) could reduce passenger vehicle fuel consumption by as much as 44% (U.S. Energy Information Administration 2017).

In order to realize the safety, mobility, cost, and environmental benefits, a major emphasis

on network security and privacy protection are required.

Security

Vehicles are considered as the first personally owned device that relies on real-time network communication to ensure driver, passenger, and pedestrian’s physical safety. For this reason, ad-hoc vehicle networks must provide security services. The revolving door of highly-mobile devices into and out of the network requires a continuous provisioning, revocation, and monitoring mechanism for a large number of security credentials. The security of the network also relies upon end devices and their application security.

Vehicles already depend on intra-network communications (e.g., Controller Area Network, or CAN) allowing subsystems in each vehicle to communicate and coordinate critical functionality. Widespread adoption of VANETs opens a myriad of attack vectors for adversarial manipulation of each vehicle. As a high-profile example, in 2015 an electronic control unit (ECU) in a Jeep Cherokee was compromised over a cellular network in a proof-of-concept research effort. The ECU provided direct access to the CAN bus, which was used to disable the brakes of the moving Jeep (Miller and Valasek 2015). This terrifying use of a cellular network that allowed device-to-device connectivity resulted in a recall of 1.4 million vehicles for software updates (Greenberg 2015a, b).

VANETs have several high-level security and privacy requirements to mitigate this type of compromise:

- All devices entering and remaining in the system must be certified, trusted, and function correctly.
- Vehicle and infrastructure messages must be verifiable and faithfully represent vehicle state and sender intentions. Safety-related services cannot be provided without trusted communication.

- VANETs must support near real-time communication. Network performance also affects safety.
- Unauthorized information disclosure should be prevented.
- Vehicle owners' privacy, such as illegitimate access to their current or past location, must be prevented unless permission is given (Beresford and Stajano 2003).
- Non-repudiation should be supported. Each message must be traceable by an authority to the sender without breaching a person's right to location privacy.

Cryptosystems form the security foundation and provide message confidentiality, integrity, and authentication in the ad-hoc network. Most encryption strategies use asymmetric key cryptography and manage key distribution using one or more Public-Key Infrastructures (PKI). In a PKI, one or more private and a public key pairs are used for security operations. Public keys have defined validity periods and are signed by authorities to generate certificates releasable to anyone. Message trust is provided through a chain of certificates from an end-entity certificate (e.g., vehicle) to a single root of trust. Verification of digital signatures establishes their trustworthiness.

Elliptic Curve Cryptography (ECC) is well-suited to meet the real-time requirements of vehicular networks, since keys are small relative to their security strength. Fast ECC hardware and software implementations are available and well-tested. Specially protected hardware has been recommended for vehicle-based devices to protect private keys and critical security operations (FIPS 2001; NHTSA 2017a).

Some component (or a set of components) of the PKI must be able to trace each message signature to the signer. A message that does not represent the true state of the sender or is intended to do harm is indicative of misbehavior. Misbehavior may be unintentional, in the case of a malfunctioning vehicle, or it may be intentional, in the case of messages under a compromised certificate. Any form of misbehavior must be detected, reported, adjudicated, and *all the*

certificates issued to a misbehaving device must be identified and communicated to the remaining system participants.

Communication between vehicles and infrastructure (V2I, I2V) can follow traditional network security protocols with one exception: protecting driver location privacy. Infrastructure should be prevented from tracking vehicles unless given permission.

The DSRC security functions specified in the IEEE 1609.2 standard address vehicle impersonation, malicious harm to vehicles, traffic misrouting, signal tampering, and denial-of-service. Effective authentication and non-repudiation can mitigate the majority of these threats. Without authentication, false messages pose a significant safety and operational risk to drivers. In the USA, authentication services specified in IEEE 1609.2 are realized in the Security Credential Management System (SCMS) (Brecht et al. 2018). SAE J2945 provides additional security requirements for vehicle on-board equipment. Non-repudiation and authentication is assured through digital signatures. Even with authentication, denial of service attacks remains a problem. Security services are required to authenticate a portion of the messages they receive and false, but correctly formatted, messages will tie up resources.

In C-V2X, data integrity and confidentiality in V2I and I2V communication is primarily provided through encryption after device authentication. Encryption keys are established using the LTE Authorization and Key Agreement (AKA) protocol. The AKA protocol identifies devices and necessitates interaction with infrastructure; therefore, it is ill-suited for D2D communications. Privacy-preserving, V2V communication over C-V2X will require an alternative authentication mechanism to what is provided today.

Privacy

Today, over 1 billion people use mobility applications to plan routes and avoid traffic (Perez 2016). Vehicle owners, policy makers, and ITS designers recognize the value of real-time location data generated by vehicles and transported

across the network. These applications provide a significant consumer value, but they collect location information from all users in order to provide a service; unfortunately, most drivers fail to consider the larger privacy implications of these applications.

V2V privacy requirements in a vehicular ad-hoc network necessitate authentication without identification. Privacy designs proposed for vehicular ad-hoc networks include short-lived identifiers (pseudonyms), shared identifiers, and privacy-preserving cryptography (Zhang and Delgrossi 2012). In the United States, standards (e.g., SAE J2735 and J2945) currently ensure broadcast messages do not contain persistent identifiers. For example, radio MAC and IP addresses are changed periodically along with security certificates.

When using short-lived pseudonyms, proximate vehicle populations should synchronize pseudonym changes. This is because even small differences in pseudonym change times may aid an adversary in linking a vehicle's pseudonym before and after the change. Short-lived pseudonyms can protect driver's privacy in the following strategies:

1. Vehicles are provisioned batches of unique pseudonym certificates by a PKI authority; each certificate has a short validity period.
2. Vehicles are provisioned batches of shared pseudonym certificates by a PKI authority; each certificate has a short validity period.
3. Vehicles are provisioned a group certificate by a PKI authority; the private key associated with the group certificate allows the vehicle to become its own certificate authority and generate short-lived pseudonym certificates as needed (a hybrid system).

Ideally, a different pseudonym certificate would authenticate each message to better protect driver privacy. However, if each vehicle in the USA drove for 30 min, 4.5 trillion certificates would be needed each day. Generating and provisioning this many certificates is unreasonable, and the amount of computation needed to support security and privacy operations increases

when pseudonyms change. Therefore, the verify-on-demand authentication strategy (Krishnan and Weimerskirch 2011) has been proposed to mitigate such overhead in large vehicle populations. In addition, smaller batches are supplied to each vehicle and vehicles use a pseudonym for a short period of time (e.g., 5 min) can re-use the same pseudonym in a subsequent period. Strategy 2 provisions the same certificate to multiple vehicles. Shared certificates provide exceptional privacy protection; however, revocation of one certificate can have unintended effects on those that share the certificate.

Future Directions

On the dawn of VANET deployment, more changes are expected in the transportation industry in the next 5–10 years than the previous 50 years (Burke 2016; Barra 2016). VANETs promise to improve transportation safety and efficiency, but without careful design VANETs may threaten user security and privacy.

While VANETs are poised for widespread deployment and adoption, fundamental infrastructure for hosting VANETs are in flux, DSRC, and C-V2X being the leading possibilities. VANETs provide real-time situation awareness to vehicles and infrastructure-based services. They will be the foundation of an ITS that will benefit society in four key areas: safety, mobility, cost, and environmental protection. Yet, for the abounding benefits afforded by VANETs, security and privacy vulnerabilities will lead to catastrophic consequences if left unprotected. Developments to build security into VANETs are essential. The privacy ramifications of such a network and the valuable data it transports are in the nascent stages of being studied.

Finally, to reap the promised benefits of VANETs, integrating novel technologies with legacy vehicle systems is a challenge that must be addressed. In particular, the fast-paced evolution of communication technology and the long-lived ownership model of personal vehicles. VANET-enabled technologies must adapt to work both

functionally and securely with industry-adopted, proven systems, such as intra-vehicle CAN networks.

Fifth generation wireless (5G) uses millimeter waves to boost communication bandwidth and decrease latency. It will allow new types of data to be transmitted in near real time. As an example, vehicle perceptions of their environment could be shared over 5G networks. This capability may help facilitate autonomous driving and issue in entirely new ways to get from place to place.

Definitions

Vehicular ad hoc networks (VANETs) are classified as an application of mobile ad hoc network (MANET) that has the potential in improving road safety and in providing travelers comfort (Rasheed et al. 2017). VANETs were first mentioned and introduced (Toh 2002) under “car-to-car ad hoc mobile communication and networking” applications, where networks can be formed and information can be relayed among cars. It was shown that vehicle-to-vehicle and vehicle-to-roadside communication architectures will coexist in VANETs to provide road safety, navigation, and other roadside services. VANETs are a key part of the intelligent transportation system (ITS) framework. The nodes in VANETs collect the information about themselves and the environment around them by the installed variety of sensing equipment, transfer the information to central processing unit by communication technology, and analyze the information by computing technology to obtain the optimal path, report the road timely, and arrange the light cycle.

Historical Background

Vehicular ad hoc network (VANET) typically addresses the issue about alerting drivers about the conditions of roads, traffic, and related aspects that are crucial to safety and to the regulation of vehicle flow. Vehicular ad hoc networks are also called inter-vehicle communications (IVC) or vehicle-to-vehicle (V2V) communications. VANET or IVC has drawn a significant research interests from both academia and industry. One of the earliest studies on IVC was started by JSK (Association of Electronic Technology for Automobile Traffic and Driving) of Japan in the early 1980s. Since 2002, with the rapid development of wireless technologies, the number of papers on VANET or IVC has been dramatically increased in academia, and various new workshops were created to address research issues. On the other

hand, several major automobile manufacturers, such as Audi, BMW, and Fiat, have already begun to invest inter-vehicle (C2c 2006). IEEE also formed the new IEEE 802.11p task group which focuses on providing wireless access for the vehicular environment networks and published the formal 802.11p standard in 2010. VANETs comprise of communication-enabled vehicles which act as mobile nodes as well as routers for other nodes, which has its unique characteristics as follows Li and Wang (2007), Jakubiak and Koucheryavy (2008), Toor et al. (2008), and Al-Sultan et al. (2014):

- Highly dynamic topology and frequently disconnected network. Due to high speed of movement between vehicles, the connectivity of the VANETs could also be changed frequently, and the topology of VANETs is always changing. Especially when the vehicle density is low, it has higher probability that the network is disconnected.
- Sufficient energy and storage. The nodes in VANETs are vehicles, which can be equipped with a sufficient number of sensors and computational resources, such as processors, a large memory capacity, advanced antenna technology, and global position system (GPS). These resources can help nodes to have ample energy and computing power (including both storage and processing).
- Mobility modeling and predication. Due to highly mobile node movement and dynamic topology, mobility model and predication play an important role in network protocol design for VANETs. Moreover, vehicular nodes are usually constrained by prebuilt highways, roads, and streets, so given the speed and the street map, the future position of the vehicle can be predicated.
- Variable network density. The network density in VANET varies depending on the traffic density, which can be very high in the case of a traffic jam, or very low, as in suburban traffic.
- Geographical type of communication. Compared to other networks that use unicast or multicast where the communication end

points are defined by ID or group ID, the VANETs often have a new type of communication which addresses geographical areas where packets need to be forwarded (e.g., in safety driving applications).

- Various communication environments. VANETs are usually operated in two typical communication environments. In highway traffic scenarios, the environment is relatively simple and straightforward (e.g., constrained one-dimensional movement), while in city conditions it becomes much more complex. The streets in a city are often separated by buildings, trees, and other obstacles. Therefore, there isn't always a direct line of communications in the direction of intended data communication.

Foundations

MANETs generally do not rely on fixed infrastructure for communication and dissemination of information. VANETs follow the same principle and apply it to the highly dynamic environment of surface transportation. The architecture of VANETs consists of three layers: the end layer, the communication layer, and the cloud layer which is shown in Fig. 1

- The end layer: A variety of smart sensors are mounted on vehicles, which are responsible for acquisition of the vehicle's intelligent information and perception of driving condition and the environment. All these information are gathered in onboard unit (OBU), which is the terminal taking charge of the interior vehicle communication, inter-vehicle communication, and the communication between vehicles and other unit, like cloud server and road side unit (RSU); at the same time, OBU enables the vehicles addressing and having trusted network identification.
- The communication layer: VANETs can be formed by cellular, wireless local area

Vehicular Ad Hoc Network, Fig. 1 VANETs architecture

network (WLAN) and ad hoc way which solve the problem of connectivity between the vehicle and the vehicle (V2V), vehicle and road (V2R), vehicle to infrastructure (V2I), and vehicle to home (V2H). The communication layer realizes vehicle ad hoc network and a variety of communication and roaming between heterogeneous networks ensure real-time performance, serviceability, and network generality on the function and performance. A standard, dedicated short-range communication based on IEEE 802.11p has been established.

- The cloud layer: The cloud layer receives multisource massive amounts of information, which can be audio, video, pictures, and so on, from VANETs. The cloud layer not only receives and stores these information but also analyzes and processes these information and provides a variety of services utilizing these information. These services can be logistics, vehicle repairing, car rental, insurance, emergency rescue, mobile Internet, and so on. This layer is a complex system around the vehicle's data gathering, calculation, scheduling, monitoring, management, and application.

Key Applications

VANETs support a wide range of applications from simple one-hop information dissemination to multi-hop dissemination of messages over vast distances. These applications can be classified according to their primary purpose into safety-related application and client-based application (Toor et al. 2008; Kumar et al. 2013; Martinez et al. 2010):

- Safety-related applications: This category of applications is referred to traveler's safety and management of vehicle traffic on the streets. These applications gather information through the vehicles' sensors in the whole network, process these information, and disseminate the analysis results to all vehicles.
 - Collision avoidance systems lead to the avoidance of many road accidents; these systems are based on the communication between vehicles or between vehicles and infrastructure. This category of applications is designed to send warning messages to vehicles to warn the driver about the current dangerous situation, like the traffic signal, the stop signal, and the intersection.

- Cooperative driving allows vehicles to closely (down to a few inches) follow a leading vehicle by wirelessly receiving acceleration and steering information, thus forming electronically coupled road trains.
- Public safety: where VANET communications, VANET networks, and road safety warning and status information dissemination are used to reduce delays and speed up emergency rescue operations to save the lives of those injured.
- Traffic enhancement: which uses VANET communication to provide up-to-the minute obstacle reports to a vehicle's satellite navigation system.
- Client-based application: These applications provide services with the entertainment (audio, video, game, etc.) and advertising (shops, gas stations, restaurants, etc.). This category of applications is also referred to as non-safety applications and aims to improve drivers and passengers comfort levels (make the journey more pleasant) and enhance traffic efficiency. They can provide drivers or passengers with weather and traffic information and detail the location of the nearest restaurant, petrol station, or hotel and their prices. Passengers can play online games, access the Internet, and send or receive instant messages while the vehicle is connected to the infrastructure network.

Standards

Major standardization of VANET protocol stacks is taking place in the USA, in Europe, and in Japan, corresponding to their dominance in the automotive industry. In the USA, the IEEE 1609 WAVE (Wireless Access in Vehicular Environments) protocol stack builds on IEEE 802.11p WLAN operating on seven reserved channels in the 5.9 GHz frequency band. The WAVE protocol stack is designed to provide multichannel operation (even for vehicles equipped with only a single radio), security, and lightweight application layer protocols. Within the IEEE Communications Society, there is a Technical Subcommittee on Vehicular Networks

and Telematics Applications (VNTA). The charter of this committee is to actively promote technical activities in the field of vehicular networks, V2V, V2R, and V2I communications, standards, communications-enabled road and vehicle safety, real-time traffic monitoring, intersection management technologies, future telematics applications, and ITS-based services.

Protocols

Protocols are a very important issue in VANETs which have been researched by researchers for many years. These protocols all primarily aim to maximize throughput while minimizing packet loss and controlling overhead. One of the major technological challenges faced by VANETs is developing an efficient routing protocol for a highly changeable topology. The current VANET routing protocols can be divided into groups as follow:

- Topological-based routing protocol. This class of routing protocols employs the link information that exists in the network to execute packet forwarding, and the protocols are categorized as (1) proactive (table-driven) routing, which mainly depends on the shortest path algorithms; (2) reactive (on-demand) routing, which is known as on-demand routing protocol because they regularly renew the routing table; and (3) hybrid routing, which are a combination of the reactive and proactive routing protocols to make routing more scalable and efficient.
- Cluster-based routing protocol. Cluster-based routing protocols are more suitable for network cluster topology. Every cluster has one cluster head which is responsible for intra- and inter-cluster management purposes. The intra-cluster nodes interact with one another through direct links, whereas inter-cluster interaction is performed through the cluster headers. The configuration of clusters and the choice of the cluster head are an important issue in cluster-based routing protocols.

- Geocast-based routing protocol. Geocast-based routing is a position-based multicast routing employed to forward a message to all the vehicles in a fixed topographical area. The main goal of this approach is to distribute the packet from the source node to all the other nodes in a particular geographical area or zone of relevance.
- Multicast-based routing protocol. Multicast transmission in the VANET is typically a transmission from a single source to multiple destinations within a specific geographic region and is usually conducted via geocast routing. VANETs are beneficial for multicast protocols because of their wireless nature, which allows a message sent by a node to be broadcast to all nodes within range. VANET nodes do not have to conserve power because vehicles provide substantial power supply for long durations, which enables the nodes to perform complex computational tasks.
- Position-based routing protocol. In position-based routing protocols, all nodes recognize their own locations and their neighbor node geographic locations through position-pointing devices such as GPS. It does not manage any routing table or exchange any information related to the link state with the neighbor nodes. The information from the GPS device is used in making routing decisions. The position-based routing protocols can be classified as non-delay-tolerant network (non-DTN) routing protocols, delay-tolerant network (DTN) routing protocols, and hybrid routing protocols.

Simulations

Prior to the implementation of VANETs on the roads, realistic computer simulations of VANETs using a combination of urban mobility simulation and network simulation are necessary. Typically open-source simulator like SUMO (which handles road traffic simulation) is combined with a network simulator like NetSim (TETCOS), to study the performance of VANETs. A study of cooperative automated driving (Llatser et al. 2017) using Webots and NS3 simulators before

real road test has been performed in the context of the AutoNet 2030 European project.

Definition

Verifiable cloud computing is a way to provide cloud computing services that outsource comput-

ing to untrusted third parties while maintaining the integrity of the computation results.

Historical Background

In cloud computing, the data owner outsources the data storage and query services to a cloud service provider in order to scale up the services with a low cost. However, such an outsourcing model brings about serious issues in computation integrity. As the service provider is not the real owner of the data, it might return incomplete or incorrect results, intentionally or unintentionally. Thus, to ensure computation integrity, the client needs to authenticate the soundness (every result originates from the data owner's database), the completeness (no valid result is missing), and the freshness (the result is up-to-date) of the computation results. To tackle this problem, one early solution is *verification by replication* (Haeberlen et al. 2007). The idea goes as follows. The client outsources the same computing task to multiple workers of different service providers. If not enough results are returned within a reasonable time or the results do not agree, the client would send the task to more other workers. Once a minimum number of the workers agree on the same computation results, the client assumes those results are correct. Although this solution is simple and effective, it assumes failure independence, which however does not hold when facing malicious service providers. In order to provide strong guarantee on the integrity of the computation results against untrusted or even malicious service providers, cryptographically enforced verifiable cloud computing is proposed and studied by a large body of literature. The basic idea is that the service provider should return not only the computation results but also a cryptographic proof, which can be used by the client to establish the soundness, completeness, and freshness of those results.

There are several metrics when it comes to evaluate the verifiable cloud computing protocols: (i) preprocessing time, which is the time for the data owner to generate some auxiliary data such as authenticated data structure; (ii) proving

time, which is the time for the service provider to compute the proof; (iii) verification time, which is the time for the client to verify the proof; and (iv) proof size. It is worth noting that the verification time and proof size should ideally be proportional to the size of the computation results and be independent to the size of the whole database. This is particularly important when the client is a mobile user connecting to the cloud through a wireless network.

Foundations

In general, there are two fundamental approaches to support verifiable cloud computing, each with its own advantages and disadvantages. On the one hand, one can design a verifiable scheme specifically based on the computation task. This is often achieved by letting the data owner sign a well-designed *authenticated data structure* (ADS), based on which the service provider can construct corresponding proofs for the outsourced computation. This approach yields low overhead but supports only limited computation tasks. On the other hand, a verification scheme may model the computation task as a general Turing machine. As such, they can support arbitrary tasks at the expense of high and sometimes impractical overhead.

For the ADS-based verification schemes, there are two basic techniques: signature chaining (Fig. 1) and Merkle hash tree (Fig. 2). The former technique uses a public-key cipher with which the data owner can generate digital signatures for each data item using a private key. Consequently, the client can verify the authenticity of the data item using the public key. To establish the completeness of the query results, chaining signatures are generated to capture the correlation of each item and its adjacent items (Pang and Tan 2004). Merkle hash trees (MHTs), on the other hand, are built on index trees (Merkle 1989). Each entry in a leaf node is assigned a digest based on its hashed value, and each entry in an internal node is assigned a digest derived from its child nodes. The data owner signs the root digest of the MHT, which can be used to

Verifiable Cloud Computing, Fig. 1 Signature chaining

verify any subset of data items. For example, in Fig. 2, a range query Q will return $\{o_2, N_2, N_3\}$, based on which the client can reconstruct the root digest $N_0 = h(h(N_3|h(o_2))|N_2)$ for verification. MHT has been widely adapted to various index structures. Typical examples include the Merkle B-tree for relational data (Li et al. 2006), the Merkle R-tree for spatial data (Yang et al. 2009b; Yiu et al. 2011), the authenticated inverted index for text data (Pang and Mouratidis 2008), the graph metric tree for subgraph similarity search (Peng et al. 2015), and the authenticated prefix tree for multisource data (Chen et al. 2015). It has also been adopted to support authenticated join queries (Yang et al. 2009a), verifiable privacy-preserving location-based services (Hu et al. 2012, 2013; Chen et al. 2013), and queries with fine-grained access control (Xu et al. 2018b). More recently, there have been studies of the ADS schemes on the set-valued data (Papamanthou et al. 2011; Canetti et al. 2014; Zhang et al. 2017b). They utilize a cryptographic set accumulator, which is able to present a (multi-)set with a constant-size digest and support a variety of verifiable (multi-)set operations such as subset, set disjoint, set sum, set intersection, and set union. Based on that, one can achieve verifiable query processing over high-dimensional data (Papadopoulos et al. 2014), verifiable SQL processing (Zhang et al. 2015), or verifiable analytics aggregation queries (Xu et al. 2018a).

In comparison, the general-purpose verifiable cloud computing scheme does not assume any specific properties on the computation task. Instead, the computation task is present as a

Verifiable Cloud Computing, Fig. 2
Merkle hash tree

Boolean or arithmetic circuit, which is Turing complete and thus can be used for arbitrary cloud computation. As the Boolean or arithmetic circuit can be viewed as a series of constraints on the internal computation state as well as the final results, it can be transformed into a so-called quadratic span program. By utilizing certain cryptographic primitives such as pairing, the equivalent program can be verified using a technique known as zk-SNARKs (Parno et al. 2013). In addition to the ability to authenticate arbitrary programs, zk-SNARKs is able to achieve extremely low overhead on verification. The verification time and proof size are both in constant. Further, it leaks no information beyond the computation result, which is crucial for the applications with privacy and confidentiality concerns. However, as a cost of its generality, zk-SNARKs yields high overhead on the preprocessing time and proving time. It is considered impractical to many real-world cloud computing problems. Nevertheless, many studies have been carried out to reduce its proving overhead. Ben-Sasson et al. (2014) propose a zk-SNARK variant that avoids hard-coding the computation program into its verification key and thus reduces the preprocessing cost. Zhang et al. (2017a) propose an interactive protocol for general-purpose SQL queries, whose cost is substantially lower than the original zk-SNARKs scheme. More recently, it has been proposed to model the computation task as a *random access machine* (RAM) program as opposed to a circuit (Braun et al. 2013; Ben-Sasson et al. 2013; Zhang et al. 2018). As a result, it can gain significant performance improvement for some computation tasks. For example, the size of a circuit implementing binary search on a sorted

array is linear in the length of the array, whereas the complexity of a RAM program for binary search is only logarithmic.

Key Applications

Verifiable cloud computing is essential in every cloud computing environment that has security and trust concerns. For example, it is imperative for the application scenario where business intelligence executives make critical, million-dollar decisions such as investing in new businesses based on OLAP queries in the cloud. Similar requirements also exist in many other applications such as scientific research and government policy making.

Video streaming over vehicular networks

Definitions

As one of the most important enabling technologies in the envisioned intelligent transportation system (ITS), vehicular networks are designed to provide information exchange via vehicle-to-vehicle (V2V) and vehicle-to-infrastructure (V2I) communications.

Historical Background

With the explosive growth of information technology, vehicular networks contribute to a more efficient driving experience by acting as a promising medium to provide a number of innovation applications, such as traffic monitoring, driving assistance, and multimedia services (Belanović et al. 2010; Ren et al. 2015; Wu et al. 2018).

Vehicular networks employ two different transmission categories, i.e., vehicle-to-infrastructure (V2I) communications, which enable vehicles to communicate with a roadside unit (RSU), and vehicle-to-vehicle (V2V) communications, which enable vehicles to communicate with each other. In 1999, FCC allocated 75 MHz (from 5.850 to 5.925 GHz) bandwidth for dedicated short-range communication (DSRC) in vehicular environments. The IEEE 802.11p/1609 Wireless Access in Vehicular Environment (WAVE) protocol (IEEE Std. 802.11p 2010) and US Department of Telecommunication (US DOT) Federal Highway

Administration DSRC RSU specification document (Chang et al. 2017) have been proposed as the standards for vehicular networks. Meanwhile, the development of cellular communication-supported vehicle-to-everything (V2X) services (3GPP TR 22.885 2015) also received a significant amount of attention from both the industry and academia. Cellular systems, such as Long-Term Evolution (LTE) (Zhou et al. 2015, 2017), are considered as a promising technique for vehicular communication due to their excellent properties, such as high data rate, low latency, large coverage area, high energy efficiency, robust interference control, high penetration rate, and high-speed terminal support (Araniti et al. 2013).

Video streaming over vehicular networks has considerable benefits for both entertainment and road safety. However, high-quality video streaming for fast-moving vehicles encounters fundamental challenges that are attributed to the high mobility and dynamic nature of a network.

Foundations

Channel Estimation in Vehicular Networks

Due to the high mobility of vehicles, the channel condition of each V2I/V2V link may change dramatically during one scheduling period for video streaming. According to Mecklenbrauker et al. (2011), the maximum Doppler frequency in V2V communications can be four times higher than the maximum Doppler frequency in cellular scenarios with the same velocity, which indicates that the time-varying characteristics of vehicular environments are prominent. Therefore, precise channel condition estimation scheme is important and essential for V2I/V2V communications in vehicular networks.

Akhtar et al. perform a realistic analysis of the vehicular network topology characteristics over time and space for a highway scenario (Akhtar et al. 2015). Their investigation results suggest that the most simplistic channel models, including lognormal and unit disk models, fail to provide realistic vehicular network topology characteristics. They further propose a matching

mechanism to tune the parameters of the lognormal model according to the vehicle density and a correlation model to take into account the evolution of the link characteristics over time. The parameters of the proposed model are validated to depend only on the vehicle traffic density based on the real data of four different highways in California.

The substantially predictable vehicle movement makes it possible to estimate the vehicle trajectory in vehicular networks. One can use the position information to obtain partial channel state information (CSI), i.e., the path loss of the channel based on the transceiver distance. The work of Cheng et al. (2015) suggests that resource allocation which utilizes the path loss-based channel state instead of the full CSI is more suitable for vehicular networks; i.e., considering both the path loss and fast fading would not be efficient and effective due to the movement of vehicles.

Video Streaming Over 802.11p-Based Vehicular Networks

Rezende et al. propose a Video Reactive Tracking-based Unicast (VIRTUS) protocol for unicast streaming over vehicular networks (Rezende et al. 2012, 2015). Their research focuses on the suitability of a node to relay packets based on the balance between geographic advancement and link stability. VIRTUS is a reactive solution as its forwarding mechanism is receiver based. It means instead of forwarding nodes choosing the next hop in the route, receiving nodes are responsible for determining if they are supposed to relay the packet. If a node overhears a node closer to the destination forwarding the same packet that it has previously scheduled before its own waiting time expires, it drops the packet.

Asefi et al. propose an adaptive retransmission limit selection scheme to improve the performance of the IEEE 802.11p protocol for video streaming applications over vehicular networks (Asefi et al. 2012). They propose a multi-objective optimization framework to be applied at RSU, which jointly minimizes the probability of playback freezes and start-up

delay of the streamed video at the destination vehicle by tuning the MAC retransmission limit with respect to channel statistics as well as packet transmission rate. Periodic channel state estimation is performed at the RSU using the information derived from the received signal strength (RSS) and Doppler shift effect. Estimates of access probability between the RSU and the destination vehicle are incorporated in the design of the adaptive MAC scheme.

Xing et al. propose an adaptive scheme for scalable video coding (SVC) video streaming services in a highway scenario, where a vehicle can download video data using a direct link or a multihop path to the RSUs via cooperative relay among vehicles (Xing and Cai 2012). Considering the current download speed and the receiver buffer level, the proposed scheme can request an appropriate number of video enhancement layers to improve video quality of experience (QoE).

Belyaev et al. develop and validate a video transmission system for road surveillance applications. They propose low-complexity unequal packet loss protection and rate control algorithms for SVC based on a 3-D discrete wavelet transform (Belyaev et al. 2015). In comparison with a scalable extension of the H.264/AVC standard, the proposed codec is less sensitive to packet losses, has less computational complexity, and provides comparable performance in case of unequal packet loss protection. Measurements obtained in realistic city traffic scenarios demonstrate that good visual quality and continuous playback are possible when the moving vehicle is in the radius of 600 m from the roadside unit.

Video Streaming Over Cellular Communication-Supported Vehicular Networks

Some existing researches focus on video streaming over noncooperative vehicular networks, i.e., V2I communication only. An et al. propose a Resource Allocation and Layer Selection (RALS) algorithm (An et al. 2016) for SVC video streaming scheduling problem, which explicitly takes account of the utility value of each group of picture (GOP) among all the

vehicular users. Xu et al. (2015) introduce a dynamic programming-based resource allocation algorithm for SVC streaming over vehicular networks. Zhou et al. (2016) investigate the resource allocation problem for video multicast services over vehicular networks to answer the questions of which modulation and coding scheme (MCS) should be adopted for each flow in each time segment and how to schedule the radio resources among all the flows. For the multicast service to cover all the recipients, a k-commodity packing-based approximation algorithm is proposed to solve it with low complexity. For the multicast service with adaptive recipients, a heuristic algorithm is proposed to search for proper MCS profile assignments.

As for cooperative vehicular networks, the scheme proposed by Yaacoub et al. is based on grouping moving vehicles into cooperative clusters (Yaacoub et al. 2015). As shown in Fig. 1a, the LTE system is used to send data over long-range cellular links to a selected cluster head, which multicasts the received video over IEEE 802.11p links to vehicles in its cluster. Error concealment techniques are used to compensate the loss of frames that are not delivered on time for real-time video streaming. In addition, resource allocation to select the best subcarriers for LTE transmission is performed in order to enhance the received video quality.

As shown in Fig. 1b, Zhou et al. (2018) consider SVC video streaming over another type of cooperative vehicular networks where the V2I communications are based on LTE links

and the V2V communications occur via another OFDMA-based system using a band of DSRC or a dedicated portion of the LTE band for device-to-device (D2D) communications in overlay mode. They investigate the joint optimization problem about the number of video layers that should be transmitted for each vehicle, the selection of relay vehicles to assist destination vehicles, and the assignment of radio resources to direct and cooperative communications. The optimization problem is decoupled into two subproblems. The lower-level quality of service (QoS)-driven resource allocation subproblem is solved as a generalized maximum concurrent flow problem, and the high-level layer selection subproblem is solved using a tabu search-based metaheuristic algorithm.

Key Applications

Video streaming over vehicular networks is important for both entertainment and road safety services.

For instance, video is the desired media for delivering advertisements and news, which provide passengers with a vast amount of information, more options for entertainment, and higher office efficiency (Zhou et al. 2014; Xing et al. 2016; He et al. 2016). Emergency-related video streaming also has an important role in enhancing road safety (Park et al. 2006; Zhuang et al. 2011).

Future Directions

Vehicular Networks Driven by Deep Learning

With rapid development of artificial intelligence, deep learning has been successfully applied in many areas, including computer vision and speech recognition, and has drawn a lot of attentions of researchers in the vehicular network area (Ye et al. 2018).

In Atallah et al. (2018), the deep reinforcement learning model, namely, deep Q-network, is investigated to learn a scheduling policy from high-dimensional inputs corresponding to the current characteristics of the underlying model. In Sheng et al. (2018), the deep reinforcement learning method has also been used for resource allocation problem in vehicular networks.

However, more studies should be conducted to apply deep learning in vehicular networks. For example, more theoretical analysis should be done to provide guidelines on the architecture design of neural networks and the selection of hyper-parameters.

[Mobile data offloading techniques in Wi-Fi-cellular networks](#)

Definitions

- *WiFi offloading in Wi-Fi-cellular networks:* WiFi offloading is a promising solution that can cope with the mobile data explosion by migrating traffic from cellular networks to WiFi networks.

Historical Background

For the last several years, the increasing number of wireless devices has lifted mobile data traffic

to a great extent around the world. According to the recent report (Cisco 2017), the compound annual growth rate (CAGR) of the global mobile data traffic is forecasted as 47% from 2016 to 2021. In addition, the global mobile data traffic is expected to grow to 49 exabytes per month by 2021, which is a sevenfold increase over 2016.

To cope with the traffic growth, one of the most straightforward solutions is to increase the cellular network capacity by installing additional base stations (BSs) (e.g., conventional macroBSs and femtoBSs). However increasing the cellular network capacity requires expensive capital expenditure (CAPEX) and operation expenditure (OPEX) (Jung et al. 2014). Also, with the respect to cellular network operators, increasing the capacity is not cost-efficient under a flat price policy where the revenue is independent of data usage.

In this context, leveraging existing radio access technologies (RATs) in heterogeneous networks to offload mobile data traffic can be a practical approach. That is, a mobile node (MN) is capable of accessing various RATs and migrates its traffic from cellular networks to femtocell or WiFi networks. Specifically, since WiFi access points (APs) are widely deployed and they have low CAPEX and OPEX, WiFi offloading is considered as a promising solution to address the mobile data explosion problem in which the mobile data traffic is offloaded through WiFi networks in spatially overlapped WiFi and cellular networks. In fact, WiFi offloading has been widely adopted by a large number of mobile network operators (e.g., Verizon, AT&T, T-Mobile, and Vodafone) (Juniper Research 2013).

Foundations

In general, WiFi offloading techniques can be classified into two types as follows:

- *On-the-spot WiFi offloading*: In the on-the-spot WiFi offloading technique, the data offloading is conducted only when an MN

opportunistically meets WiFi APs. That is, MNs connect to WiFi networks whenever there exists available WiFi coverage and then migrate their traffic to a WiFi network. The on-the-spot WiFi offloading technique is the simplest WiFi offloading technique, and it is provided in most of the current smartphone platforms.

- *Delayed WiFi offloading*: In the delayed WiFi offloading technique, the data transfer is delayed with the expectation of future AP contacts. That is, an MN delays data traffic of delay-tolerant applications (e.g., file downloads) up to the predefined delay threshold until a WiFi network becomes available. During the delay threshold, if a WiFi network becomes available, the MN immediately starts the pending data session through the WiFi network.

Figure 1 describes the WiFi offloading scenario in heterogeneous networks where WiFi APs are sparsely deployed within cellular coverage. The detailed procedures of each WiFi offloading technique can be described as follows. Consider a scenario where an MN attempts to establish a data session to download/upload a file from/to the Internet at time t . It is assumed that a cellular network is always available, whereas a WiFi network is only available when the MN is close enough to the WiFi AP. If any WiFi network is available at t , in both techniques, the MN establishes the data session only through the WiFi network although a cellular network is available. On the other hand, if a WiFi network is not available at t , in on-the-spot WiFi offloading, the MN uses a cellular network immediately. While for delayed WiFi offloading, the MN defers the data session up to a predefined delay bound D . During the delay bound, if a WiFi network becomes available, owing to the MN's mobility, the MN immediately starts the pending data session through a WiFi network. Therefore, the additional traffic can be offloaded to the WiFi network.

Table 1 (Lee et al. 2013) shows WiFi offloading efficiency for the on-the-spot and delayed WiFi offloading techniques, which are obtained based on WiFi connectivity 97 users for

WiFi Offloading in WiFi-Cellular Networks, Fig. 1 WiFi offloading scenario in heterogeneous networks

WiFi Offloading in WiFi-Cellular Networks, Table 1 WiFi offloading efficiency (Lee et al. 2013)

Offloading scheme	On-the-spot	100 s delay	1 h delay
Offloading efficiency/gains	65%	+(2–3%)	+29%

2 weeks. For the on-the-spot WiFi offloading, WiFi can offload about 65% of the total cellular data traffic without any delay. Meanwhile, it can be seen that the delayed WiFi offloading can offload more traffic at the cost of delay. For 100 s and 1 h delay, the achievable gains of the delayed WiFi offloading are 2–3% and 29%, respectively.

From the fields of academia, there have been several studies on WiFi offloading. The feasibility of WiFi offloading was evaluated in Mota et al. (2013) and Dias et al. (2015). Mota et al. (2013) derived the 3G and WiFi coverage through several bus routes in Paris to investigate how users and network operators can benefit from the existing WiFi infrastructure. On the other hand, Dias et al. (2015) investigated the feasibility of video streaming offloading from cellular networks to WiFi ad hoc networks.

To motivate users to participate in the delayed WiFi offloading, several incentive mechanisms were proposed in the literature (Cai et al. 2015; Zhuo et al. 2014; Lee et al. 2014; Gao et al. 2014). Cai et al. (2015) modeled an incentive mechanism by using a two-stage Stackelberg game. In the first stage, a network operator announces a uniform reward to users. After that, in the second stage, users decide whether to delay the offloading or not. Zhuo et al. (2014) proposed an incentive framework based on the reverse auction to capture dynamic characteristics on users' delay tolerance. Moreover, the authors illustrated how to predict the offloading potential of users by means of stochastic analysis. Lee et al. (2014) investigated economic gains of the delayed WiFi offloading from the perspectives of users and network operators. To this end, the authors formulated a two-stage sequential game where network operators control the price and users are price-takers. Gao et al. (2014) introduced a one-to-many bargaining game among network operators and WiFi access point owners and analyzed the interaction for the amount of data offloading and the respective compensations.

Meanwhile, some researchers investigated how to offload data from cellular networks to

WiFi networks in vehicular ad hoc networks (VANETs) (Wang and Wu 2016; Cheng et al. 2016). Wang and Wu (2016) unified the downloading cost and delay in terms of user's satisfaction and then proposed an adaptive algorithm to maximize the satisfaction. In this algorithm, a vehicle estimates the data size depending on the application type and makes a decision whether to download data through cellular networks or not. Cheng et al. (2016) suggested two WiFi offloading mechanisms (i.e., auction game-based offloading (AGO) and congestion game-based offloading (CGO)). Also, a prediction method for the WiFi offloading potential and access cost within a certain future time was proposed based on the semi-Markov process. Several offloading mechanisms through cooperative downloading for VANETs were introduced in Wu et al. (2015) and Deng et al. (2016). Wu et al. (2015) introduced an incentive-driven cluster-based content distribution mechanism to encourage cooperation. Similarly, Deng et al. (2016) proposed a prior response incentive mechanism (PRIM) to stimulate vehicles to participate in cooperative downloading.

The performance of the WiFi offloading was analyzed in Suh et al. (2016) and Mehmeti and Spyropoulos (2013). Suh et al. (2016) developed analytical models on the WiFi offloading efficiency, which is defined as the ratio of the amount of offloaded data to the total amount of data, and elaborated on the performance of WiFi offloading under diverse environments. Mehmeti and Spyropoulos (2013) proposed a queueing model as a function of WiFi availability, user mobility, and traffic load. However, in these works, how to optimize the delay timer for performance improvement was not investigated.

Few works investigated how to set the delay timer (Mehmeti and Spyropoulos 2014; Ko et al. 2017). Mehmeti and Spyropoulos (2014) proposed a queueing model for the delayed WiFi offloading, where an optimization problem for minimizing download time with cost constraints is formulated to choose the delay timer. Ko et al.

(2017) investigated the effect of the dual connectivity technology on the delayed offloading, and based on the results, they derived the optimal delay timer that can minimize the monetary cost while limiting the outage probability.

For standardization efforts, 3GPP has specified the access network discovery and selection function (ANDSF) that resides within evolved packet core (EPC) and controls offloading between 3GPP and non-3GPP access networks (e.g., WiFi) (3GPP TS 24.312 v. 11.5.0 2012a; 3GPP TS 24.312 v. 11.5.0 2012b). The key functionalities of ANDSF are to assist UEs to discover the available non-3GPP access networks in their proximity and to manage the connections to the non-3GPP access networks by prioritizing them based on operator policies.

Key Application

WiFi offloading techniques are considered as the most promising approaches that mobile operators can take to offload their mobile data traffic into WiFi networks.

Wi-Fi Protected Access (WPA)

Sheng Zhong

Nanjing University, Nanjing, China

[The draft IEEE 802.11i standard](#)

Definition

Wi-Fi Protected Access (WPA) is a security standard designed for wireless networks. WPA implements most of the IEEE 802.11i standard and was an alternative to previous security standard before 802.11i was developed, so it is sometimes referred to as the *draft IEEE 802.11i* standard.

Historical Background

WPA was developed by the Wi-Fi Alliance to provide better security than Wired Equivalent Privacy (WEP), the previous Wi-Fi security standard. WPA became available in 2003, and it was intended as a transitional measure for the full IEEE 802.11i standard (also referred to as WAP2), which became available in 2004. WAP2 may not work with some older network cards, while WPA can work well with these older network cards. Therefore, WPA and WPA2 are concurrent security standards.

There are typically two versions of WPA based on the differences in target users:

- WPA-Personal mode, also referred to as WPA-PSK, is designed for home and small office networks, which makes every user under the same wireless router use the same key called pre-shared key (PSK).
- WPA-Enterprise mode, also referred to as WPA-EAP, uses more stringent 802.1x authentication with the Extensible Authen-

tication Protocol (EAP). It needs to use an authentication server to distribute different keys to various end users.

Except for authentication, WPA also offers tremendous improvements in encryption and data integrity compared to WEP.

- **Encryption.** WEP only has a 64-bit or 128-bit encryption key which is fixed and has to be manually entered on wireless access points (APs). WPA adopts a so-called Temporary Key Integrity Protocol (TKIP), which dynamically produces a new 128-bit key for each data packet. It defeats well-known related-key attack against WEP.
- **Data integrity.** WPA also adopts a message integrity check, which is designed to prevent an attacker from altering and resending data packets, and it replaces the cyclic redundancy check (CRC) used by WEP. CRC's main drawback is that it does not provide a sufficiently strong data integrity guarantee for the packets it handles. Well-tested message authentication codes can solve these problems, but they require too much computation to be used on old network cards. WPA uses message integrity check algorithm TKIP to verify the integrity of the packets, which needs less computation but offers stronger performance than CRC.

TKIP was designed to be used with older WEP devices. However, researchers did discover a flaw in TKIP that can be used to achieve a certain attack. This caused the replacement of TKIP by CCMP (sometimes called AES-CCMP) encryption protocol in WPA2, which provides additional security.

The latest security standard for wireless networks is WPA3, which was announced as a replacement to WPA2 by the Wi-Fi Alliance in January 2018. WPA3 uses 192-bit key and individualized encryption for each user. The Wi-Fi Alliance also claims that WPA3 will mitigate security issues posed by weak passwords and simplify the process of setting up devices with no display interface.

Security Issues

There are a series of security issues in WPA.

1. **Weak passwords.** If users rely on weak passwords, WPA-PSK is still vulnerable to password cracking attacks. Brute forcing of simple passwords can be attempted using the Aircrack Suite (Tsitroulis et al. 2014). WPA3 solves this problem by requiring interaction with the infrastructure for each guessed password, so that the infrastructure may place temporal limits on the number of guesses.
2. **A lack of forward secrecy.** WPA-PSK doesn't provide forward secrecy, meaning that once an adversary discovers the pre-shared key, they can potentially decrypt all packets encrypted using that PSK. This also means an attacker can silently capture and decrypt others' packets if an access point is provided free of charge at a public place, because its password is usually shared to anyone in that place. Therefore, it's safer to use Transport Layer Security (TLS) or something similar on top of that for transferring any sensitive data.
3. **WPA packet spoofing and decryption.** The Beck-Tews attack (Tews and Beck 2009) could decrypt short packets with mostly known content, such as ARP messages, and allowed injection of 3 to 7 packets of at most 28 bytes. Halvorsen and others (Halvorsen et al. 2009) show how to modify the Beck-Tews attack to allow injection of 3 to 7 packets having a size of at most 596 bytes. The Vanhoef-Piessens attack (Vanhoef and Piessens 2013) significantly improved the Beck-Tews attack, which can inject an arbitrary amount of packets and decrypt arbitrary packets sent to a client. The vulnerability of TKIP is fixed by AES-based CCMP adopted by WPA2.
4. **KRACK attack.** The KRACK attack published in 2017 is believed to affect all variants of WPA and WPA2 (Vanhoef and Piessens 2017). Software patches can resolve the vulnerability but are not available for all devices.

Key Applications

WPA ensures that non-authorized users cannot access the wireless networks and ensure users who legitimately gain access to the networks cannot hack other devices on the same hotspot. WPA is still a configuration option upon a wide variety of wireless routing devices. A survey in 2013 showed that 71% still allowed usage of WPA and 19% exclusively supported WPA (Vanhoeft and Piessens 2013).

[Dedicated short-range communication \(DSRC\)](#); [ETSI ITS-G5 standard](#); [IEEE 1609 standards set](#); [IEEE Std 802.11p](#); [Vehicle-to-Everything \(V2X\) Communication](#); [Vehicular communication system](#)

Definition

A wireless access in vehicular environments (WAVE) system provides interoperable, efficient, and reliable radio communications in support of applications offering safety and convenience in an intelligent transportation system (ITS). In many of the ITS application scenarios, the WAVE system is designed to provide vehicles with the direct connectivity to other vehicles (V2V), to roadside (V2R), or to infrastructures (V2I) through dedicated short-range communications (DSRC). In the USA, DSRC is used to refer to radio spectrum in the 5.9 GHz band or technologies associated with WAVE. While outside the USA, DSRC may refer to a distinct radio technology operating at 5.8 GHz.

The architecture and operations of a WAVE system are based on the IEEE 1609 series of standards (IEEE 2014a) and the IEEE 802.11p standard, which is now incorporated in IEEE Std 802.11-2012. IEEE Std 1609.0 is a comprehensive guide describing the WAVE architecture and services necessary for a WAVE system. This guide is meant to be used in conjunction with IEEE Std 1609.4 (multichannel operations), IEEE Std 1609.3 (networking services), IEEE Std 1609.2 (Security Services for Applications and Management Messages),

IEEE Std 1609.11 (Over-the-Air Electronic Payment Data Exchange Protocol for ITS), IEEE Std 1609.12 (Identifier Allocations), IEEE Std 802.11 (operations outside the context of a basic service set), and other WAVE standards that may be developed to specify higher layer, application, or features.

A WAVE device is a device compliant to the IEEE 1609 standards and IEEE Std 802.11 and supporting the information exchange with other WAVE devices. Typical WAVE devices are onboard units (OBUs) mounted in onboard equipment in vehicles and roadside units (RSUs) that generally operate when stationary, which can be installed in roadside poles, traffic lights, road signs, or roadside electronic cabinets. WAVE devices adopt orthogonal frequency-division multiplexing (OFDM) and achieve a communication range of approximate 1,000 ft.

Historical Background

Intelligent transportation systems (ITSs) have been developed throughout the world since the early 1990s to improve transportation safety, traffic efficiency, and user comfort and convenience. The coordination among moving vehicles and roadside infrastructures enables high-performance traffic management, pollution reduction, and energy conservation as well.

To implement such intelligent transportation systems, wireless communications and networking have been recognized, from the beginning, as a cornerstone and play an essential role in the evolution of such systems. The IEEE has developed the WAVE architecture and associated standards to promote and standardize the widely application of ITSs. A brief context for the IEEE WAVE standards and related activities are introduced as follows.

Back in 1991, the US Congress mandated the creation of the US ITS program called Intelligent Vehicle Highway Systems (IVHS) in the 1991 Intermodal Surface Transportation Efficiency Act (ISTEA). The IVHS program is administered by the US Department of Transportation (DOT) and supported by the

nonprofit organization, Intelligent Transportation Society of America (ITSA). The program aimed at applying advanced concepts and technologies in areas of communications, navigation, and information systems to reduce traffic congestion, increase transportation efficiency, enhance mobility, improve highway safety, and reduce harm to the environment caused by automobiles (Sweeney 1993). The USDOT renamed the IVHS program into ITS program to clarify the multimodal intent.

In the mid-1990s, a national systems architecture, i.e., the National ITS Architecture, was developed by the ITS program office. Furthermore, the related ITS standards were established by USDOT in 1996 to encourage the widespread use of ITS technologies in the USA.

In 1997, the Transportation Equity Act for the twenty-first century (TEA-21) was passed, which retained ISTEA's essential features while boosting investments to promote the deployment of the USDOT's ITS program.

In 1999, the US Federal Communications Commission (FCC) allocated 75 MHz in the 5.850–5.925 GHz band to DSRC uses (FCC 2003), in response to the petition of the ITS America in 1997.

In 2004, the FCC published the DSRC Report and Order, FCC 03-324 (FCC 2004), which established standard licensing and service rules in the ITS Radio Service in the 5.9 GHz band. The published FCC 03-324 adopted the standard for the physical and MAC layers (ASTM's E2213-03 ASTM 2003), which was developed by the American Society for Testing and Materials (ASTM) based on IEEE 802.11.

In November 2004, the IEEE 802.11 Task Group p was formed to develop an amendment to the IEEE 802.11 standard to include WAVE. The specifications for higher layers in the protocol suite were developed by another IEEE team, working group 1609.

In 2006 and 2007, a set of IEEE 1609 standards, as well as IEEE Std 802.11p, were managed for trial use to demonstrate the performance of WAVE architecture and protocols. The trial-used IEEE 1609 standards include IEEE Std 1609.4–2006 (IEEE 2006b),

IEEE Std 1609.3–2007 (IEEE 2007), IEEE Std 1609.2–2006 (IEEE 2006a), and IEEE Std 1609.1–2006 (IEEE 2006c).

Since 2010, a set of full-use IEEE 1609 standards have been published. The currently active full-use standards include IEEE 1609.0-2013 (IEEE 2014a), IEEE 1609.2-2016 (IEEE 2013, 2016a), IEEE 1609.3-2016 (IEEE 2010, 2012b, 2014b, 2016b), IEEE 1609.4-2016 (IEEE 2011b, 2016d), IEEE 1609.11-2010 (IEEE 2011a), and IEEE 1609.12-2016 (IEEE 2012a, 2016c).

Foundations

Spectrum Allocation

The 75 MHz bandwidth allocated by the US FCC for DSRC usage is divided into seven 10 MHz operation channels, and the remaining 5 MHz bandwidth is reserved.

As illustrated in Fig. 1, the spectrum from 5.855 to 5.865 GHz is defined as Channel 172, while the spectrum from 5.865 to 5.875 GHz is defined as Channel 174, and so on, until Channel 184. Among all the defined seven channels, Channel 178 is used as Control Channel (CCH), while the 20-MHz Channel 175, covering Channel 174 and Channel 176, and Channel 181, merged by Channel 180 and 182, are specified as service channel (SCH). The rest Channel 172 and Channel 184 are kept for public safety applications. Specifically, according to FCC 06-110 document (FCC 2006), Channel 172 is designated for “vehicle-to-vehicle safety communications for accident avoidance and mitigation and safety of life and property applications.” Channel 184 is specified for “high-power, longer-distance

communications to be used for public safety applications involving safety of life and property, including road intersection collision mitigation.”

The IEEE WAVE standards specify two kinds of radio channel, i.e., a control channel and several service channels. The CCH 178 is used only for system management messages and WAVE Short Message Protocol (WSMP) messages. The WSMP is a protocol for rapid exchange of the messages subject to intermittent radio connectivity, which will be described in the next subsection. To reducing the delivery delay, WAVE Short Messages (WSMs) are transmitted with controllable physical characteristics and thus could be transmitted with minimal channel capacity. As a result, WSMs are allowed to use both CCH and SCHs.

The service channels are used for application data transfers as well as IPv6 traffic.

Protocol Stack

The WAVE protocol stack and the mapping of these protocol elements to IEEE WAVE standards are illustrated in Fig. 2. A data plane with protocols carrying higher layer information and a management plane for security and management functions are defined.

The full-use IEEE 1609 standards and IEEE Std 802.11p, which has been incorporated in IEEE 802.11-2012, collectively define the WAVE protocol stack.

IEEE Std 1609.3 specifies two data plane protocol stacks, the Internet Protocol Version 6 (IPv6) standard and the WSMP, which are both based on the common set of lower layer protocols including physical (PHY), medium access control (MAC) and logical link control (LLC). IEEE Std 1609.3 specifies the use of two Ethertype

Wireless Access in Vehicular Environment, Fig. 1 WAVE channels allocated by the U.S. FCC

Wireless Access in Vehicular Environment, Fig. 2 WAVE protocol stack

values, IPv6 or WSMP, in the Ethertype field in the LLC header. IEEE Std 1609.3 also specifies a WAVE Management Entity (WME).

IEEE Std 802.11p, as an amendment to IEEE 802.11, specifies several physical layers (PHYs) and one medium access control (MAC) sublayer.

IEEE Std 1609.4 specifies multichannel operations in the data plane and extensions to the IEEE 802.11 MAC sublayer management entity (MLME).

Security services for WAVE applications and management messages are defined by IEEE Std 1609.2.

IEEE Std 1609.11 specifies the first application-level protocol for Over-the-Air Electronic Payment Data exchange in ITS. IEEE Std 1609.12 standardized the used identifiers and the allocated values of the identifiers in WAVE systems.

IEEE Std 1609.0 is a guide indicating the necessary services and architecture for WAVE system.

Key Applications

The applications of WAVE systems can be classified according to their primary purposes, such as safety, efficiency, comfort, on-the-road services, or urban sensing.

- **Safety applications:** One of the most important categories of WAVE applications

is to enhance transportation safety through direct V2V or V2I communications. Example applications include forward collision warning, intersection violation warning, icy road warning, and blind spot warning. IEEE Std 1609.2 WAVE Security Services are employed to sign and authenticate such safety messages to avoid encryption when broadcasting, and the sign messages are sent using WSMP to promote bandwidth efficiency.

- **Efficiency applications:** This category of applications aim to improve the traffic efficiency of the whole urban transportation system. Representative examples are traffic lights scheduling, route planning and navigation, and electronic fee collection (EFC). The general objective of the EFC application is to conduct tolling transaction reliably and securely while vehicles pass at highway speeds. The tolling transaction should be accomplished with unambiguous association of the payer’s physical vehicle for compatibility with revenue protection violation detection and enforcement systems. The EFC transaction technology is specified by IEEE Std 1609.3, IEEE Std 1609.4 and IEEE Std 1609.11.
- **On-the-road services:** The service information received by drivers on-the-road makes the trips more comfortable and enjoyable. Such information includes weather information,

point-of-interest locations, advertisement of on-going sales, and available parking lot.

- **Urban sensing:** Based on the V2V and V2I communications, the WAVE systems also support urban monitoring and sensing when vehicles are equipped with onboard sensors. The photos and videos of road conditions, driving speeds of vehicles, or collision or emergency alerts could be shared among vehicles or through Internet for large-scale urban monitoring and efficient sensing data collection.

Synonyms

[Wireless big data](#)

Definitions

Wireless big data describe massive data (e.g., wireless signaling data, device logs, browser history, and payment records) generated by wireless networks (e.g., cellular networks, wireless sensor networks, and wireless ad hoc networks), as well as related technologies for data collection and analytics.

Historical Background

Similar to the traditional concept of big data, wireless big data can be also described by four “V”: volume, variety, velocity, and value.

In addition, wireless big data show unique characteristics of large-scale distribution and strong heterogeneity, which impose additional challenges in data collection and analytics.

Wireless big data are generated everywhere in wireless networks, and their collection incurs high communication cost. In the early period, a natural approach for reducing communication cost is to sample a subset of data. In particular, compressive sampling theory (Donoho 2006) has been successfully applied in wireless sensor networks (Luo et al. 2009). It can extract global information by collecting data from a subset of sensors. Later, thanks to the significant improvement of network capacity, it becomes affordable to collect all data to avoid information missing. However, heavy network traffic generated in wireless big data collection still exists, and it can affect other applications running over wireless networks. For example, some network service providers collect system logs generated by cellular network infrastructures (e.g., base stations and switches) for network diagnosis. These traffics occupy a portion of network bandwidth, and they should be well scheduled to minimize the influence to mobile user traffic.

Meanwhile, wireless big data show heterogeneity because they are generated by various devices and applications. They have different formats and are collected with different frequencies. To provide a unified data representation, a tensor model has been proposed to represent the unstructured, semistructured, and structured data generated in wireless networks (Kuang et al. 2014). He et al. (2016) have introduced a unified data model based on the random matrix theory and machine learning.

Wireless big data can be analyzed by techniques (e.g., data mining and pattern recognition) that are also adopted by traditional big data analytics. In addition, some wireless big data can be expressed in spatial-temporal dimensions that impose additional challenges. Xu et al. (2016) design a time series analysis approach that can decompose large-scale mobile traffic into regularity and randomness components. Then, the traffic patterns can be predicted based on regularity components. In recent years, there is a growing

trend of applying machine learning techniques, especially deep learning, in wireless big data analytics. Alsheikh et al. (2016) present an overview and brief tutorial on deep learning in mobile big data analytics, as well as a scalable learning framework over Apache Spark. Yang (2016) investigates various learning methodologies for wireless big data analytics. Qian et al. (2017) survey recent research results of wireless big data analytics.

Key Applications

Wireless big data can be applied in many scenarios, such as user mobility modeling, traffic analysis, network planning, privacy, and security enhancement. Some key applications are listed as follows.

- **User Mobility Analysis:** Wireless big data generated by mobile phones have great potential for human mobility analysis. By mining wireless big data, the human mobility can be understood, predicted, or even controlled. For instance, by recording and analyzing the time spent at different locations for different individuals, it can be robustly identified whether an individual is at home or at office, which can improve the efficiency urban cellular network planning. Moreover, individual mobility and mobile traffic are closely linked to the social ecology, which helps achieve a better understanding of human behavior.
- **Social Networks:** Wireless big data also exist in various mobile social networks. Massive high dimensional personal data are collected from mobile users by the cloud. Analyzing these data can predict individual activities and provide personalized recommendation. A typical example is video recommendation. The user context data can be analyzed by a recommendation model, so that appropriate videos can be recommended for users. Meanwhile, recommendation policy can be improved according to user feedbacks.
- **Security and Privacy:** Although wireless big data can help understand individual behavior more easily, the privacy and security issues are inevitable. Wireless big data containing various privacy information, such as user locations, interests, and habits, which would be easily obtained by malicious users due to the broadcast nature of wireless transmission. Therefore, many applications concentrate on protecting privacy and security of wireless big data. For instance, using the method of distorting time, the interest and mobility habits can be concealed for achieve anonymous mobile data set.

Synonyms

[Wireless charger placement with communication constraint](#)

Definitions

Communication constraint is that if the distance of placed two chargers is less than or equal to communication radius R_c , then two chargers can communicate with each other; otherwise,

two chargers cannot communicate with each other.

Historical Background

Power transfer (WPT) technology enables the transmission of energy from a power source to an electrical load without any interconnecting cord (Lu et al. 2016). Due to its benefits such as no-wiring, no-contact, and reliability, WPT technology has been utilized in many areas such as public transportation (Mahmoudi et al. 2014), medical apparatuses (RamRakhyani et al. 2011), underwater high-power transfer system (Cheng et al. 2015), and wireless identification and sensing platform. So far, there are more than 300 million WPT commercial products in use.

A wireless charging system typically consists of multiple power transmitters, or called *wireless chargers*, and multiple power receivers, or called *rechargeable devices*. Wireless chargers commonly need to communicate with each other to exchange information like position, time, charging power, and collected data from rechargeable devices for practical purposes such as (1) collaborative scheduling to achieve certain goals such as optimization of overall charging efficiency or electromagnetic radiation safety; (2) data gathering from chargers and/or devices to a certain sink; and (3) configuration updating from a certain sink to chargers and/or devices. These purposes necessitate the need for connectivity of chargers. Besides, comparing with wired communication, wireless communication demonstrates its special advantages for enabling the connectivity of chargers, for instance: (1) it reduces the financial and labor overhead for communication line cost, layout and maintenance; (2) it is more convenient for communication establishment when chargers dynamically join or leave the network; (3) it is more reliable because communication lines expose to cutoff risks in harsh environments such as outdoor and factories; (4) it is much more preferable for mobile chargers (Madhja et al. 2015). For example, unmanned aerial vehicles equipped with wireless chargers can be

used to transmit wireless power to sensor nodes mounted on civil structures such as bridges for monitoring (Mascareñas et al. 2008); chargers can be carried by a boat to charge underwater sensor nodes (Cheng et al. 2015). Motivated by these reasons, Powercast corporation plans to embed wireless communication modules into their wireless charging products.

The problem of Connected *w*ireless Charger *p*lacement (CIRCLE) is introduced. In the considered scenario, there are some directional rechargeable devices with directional antennas distributed on a 2D plane with known positions and orientation angles. To quantify charging efficiency, charging utility for a device is given that is positively correlated with the device's aggregated received power. Suppose there needs to deploy a limited number of directional wireless chargers with directional antennas to some candidate positions on the plane to supply power to the devices. A candidate position can be placed with no more than a fixed number of chargers. The orientation angles of the chargers can be arbitrarily set. The goal is to maximize the overall charging utility for the devices under the constraint that all chargers should be connected.

There exist many works considering the wireless charger placement problem, but none of them take into account the connectivity issue regarding chargers. He et al. (2013) concerned the wireless charger placement problem where static or mobile tags must be guaranteed to receive sufficient power to keep their continuous working. Chiu et al. (2012) exploited the mobility nature of sensor nodes to improve charger deployment. Dai et al. (2016b) considered the electromagnetic radiation safety issues for wireless charger placement. There are also literatures (Dai et al. 2017) considering the directional charging property of chargers and/or devices. Moreover, there are some literatures (Horster et al. 2006; Fusco et al. 2009; Han et al. 2008) considering directional sensor placement. However, most of them are essentially geometric problems, which are fundamentally different from the considered problem and cannot be applied to address CIRCLE. In addition, some other literatures consider the problem of

maximizing a submodular set function with a connectivity constraint (Kuo et al. 2015; Huang et al. 2015; Khuller et al. 2014), which is shown to be mostly related to CIRCLE. Nevertheless, none of them can be directly used to address CIRCLE. The root reason is that CIRCLE adopt the practical directional charging model for both chargers and devices and consider the practical budget constraint for each candidate placement position.

The considered problem has three main technical challenges. The first challenge is that CIRCLE is nonlinear and NP-hard. CIRCLE is nonlinear because finding a connected subgraph in a connected graph toward a certain goal is in essence a combinatorial optimization problem, and the charging utility function is not linear. The second challenge is to design an effective algorithm with a guaranteed approximation ratio to find the placement positions for chargers with connectivity constraint. The third challenge is to select the best orientation angles for chargers from a continuous solution space.

First, a relaxed version of the nonlinear and NP-hard problem CIRCLE is considered by using omnidirectional charging models for chargers and devices, CIRCLE-R, and CIRCLE-R is proved to be a problem of maximizing a submodular set function with connectivity constraint as shown in the following Lemma 1. Thus the first challenge is addressed. Second, a new approximation algorithm to address CIRCLE-R is proposed. Most importantly, CIRCLE-R achieves an approximation ratio that outperforms the state-of-the-art algorithm by at least 1.5 times. Therefore, the second challenge is addressed. Third, to address the original problem CIRCLE, selecting the best orientation angle for each charger can be equivalently considered as a limited number of candidate orientation angles rather than all possible angles in $[0, 2\pi)$ without performance loss, and thus the third challenge is addressed.

Foundations

Because of the page limitation, our first algorithm for CIRCLE-R is introduced here, and detailed

analysis and proof are referred to the paper (Yu et al. 2018).

Network Model and Charging Model

Suppose there are N rechargeable devices denoted as $O = \{o_1, \dots, o_N\}$ in a $2D$ area Ω with fixed known positions and orientation angles. There are also a set of homogeneous B directional wireless chargers $S = \{s_1, \dots, s_B\}$ to deploy in the M candidate positions $\mathcal{P} = \{p_1, \dots, p_M\}$ that constitute a connected graph in Ω . A pair of chargers s_i and s_j can communicate with each other if their distance is not larger than R_c . The general directional charging model that is proposed in (Dai et al. 2016a, 2017) (note that the omnidirectional charging model is a special case of the directional charging model by setting the charging angle of chargers to 2π) is adopted here. As Fig. 1 shows, a charger s_i with orientation vector denoted by $\vec{r}_{\theta_i}$ can only supply power for devices in a (power) charging area as a sector region with (power) charging angle A_s and radius D . Similarly, a rechargeable device o_j with orientation vector denoted by $\vec{r}_{\phi_j}$ can only receive nonnegative power in a (power) receiving area as a sector region with (power) receiving angle A_o and radius D . Formally, the charging power from charger s_i to device o_j can be represented as follows.

$$\Pr(s_i, \theta_i, o_j, \phi_j) = \begin{cases} \frac{\alpha}{(\beta + \|\vec{s}_i \vec{o}_j\|)^2}, & 0 \leq \|\vec{s}_i \vec{o}_j\| \leq D, \\ \frac{\vec{s}_i \vec{o}_j \cdot \vec{r}_{\theta_i} - \|\vec{s}_i \vec{o}_j\| \cos(\frac{A_s}{2})}{\|\vec{s}_i \vec{o}_j\|}, & \text{and } \vec{o}_j \vec{s}_i \cdot \vec{r}_{\phi_j} - \|\vec{o}_j \vec{s}_i\| \cos(\frac{A_o}{2}) \geq 0, \\ 0, & \text{otherwise} \end{cases}$$

Wireless Charger Deployment with Communication Constraint, Fig. 1 Directional charging model

where α and β are two constant parameters which are determined by the surrounding environment (Dai et al. 2016a, 2017); $\|\vec{s}_i \vec{o}_j\|$ denotes the distance between s_i and o_j .

Moreover, when a device o_j receives power from multiple wireless chargers, the received power of o_j is from all its ambient chargers power set (Dai et al. 2016a, 2017).

Problem Formulation

Because of hardware constraints, the received power of a rechargeable device is limited to some threshold P_{th} , so the *charging utility* of a device o_j can be represented as follows.

$$U(x) = \begin{cases} c_u \cdot x, & x \leq P_{th} \\ c_u \cdot P_{th}, & x > P_{th} \end{cases} \quad (1)$$

where Eq. (1) shows that the charging utility of the device o_j is first proportional to the total received power and then becomes a constant when the total received power exceeds the threshold P_{th} . The problem of placing B directional wireless chargers toward maximizing the overall charging utility of the N rechargeable devices under the constraint that all the deployed chargers should be connected is considered. A *strategy* of a charger is defined as a two-tuple $\langle p_i, \theta_i \rangle$, where p_i is the candidate position and θ_i is the orientation angle of the charger placed at the candidate position p_i . For the same candidate position p_i , which is allowed to place at most l_{p_i} chargers, say, *budget constraint* of the candidate position. Γ_{p_i} is used to represent the set of the strategies for candidate position p_i , $\Gamma_{p_i} = \{\langle p_i, \theta_{1i} \rangle, \dots, \langle p_i, \theta_{l_{p_i}i} \rangle\}$. As there are at most B chargers, $\Gamma = \bigcup_{i=1}^M \Gamma_{p_i}$ denotes the set of strategy. With all the above definitions, the considered Connected wIReless Charger pLacement problem (**CIRCLE**) can be formulated as follows.

$$\begin{aligned} (\mathbf{P1}) \quad & \max \sum_{j=1}^N U \left(\sum_{\langle s_i, \theta_i \rangle \in A} \Pr(s_i, \theta_i, o_j, \phi_j) \right) \\ & s.t. \quad A \in F^\alpha \quad \text{and} \quad \text{Subgraph } A \text{ is connected} \end{aligned} \quad (2)$$

Approximation Algorithm for CIRCLE-R

As CIRCLE is NP-hard and difficult to be directly tackled, in this section, a relaxed version of CIRCLE (CIRCLE-R for short) is first to be considered, that is, choosing at most B connected candidate positions at which there should place one single omnidirectional charger to maximize the overall charging utility. First, the proof that CIRCLE-R is a problem of maximizing a submodular set function with connectivity constraint is given. Then, a constant approximation ratio algorithm that outperforms the state-of-the-art algorithm by at least 1.5 times in terms of achieved approximation ratio is designed.

Problem Formulation for CIRCLE-R

Recall that CIRCLE-R is to find B connected candidate positions for placing B omnidirectional chargers with optimal charging utility. Therefore, CIRCLE-R can be defined as follows.

$$\begin{aligned}
 (\text{P2}) \quad & \max \sum_{j=1}^N U \left(\sum_{s_i \in A'} \Pr(s_i, 2\pi, o_j, \phi_j) \right) \\
 \text{s.t.} \quad & A' \in \mathcal{P} \text{ and Subgraph } A' \text{ is} \\
 & \text{connected}
 \end{aligned} \tag{3}$$

where $f'(A') = \sum_{j=1}^N U \left(\sum_{s_i \in A'} \Pr(s_i, 2\pi, o_j, \phi_j) \right)$ is the charging utility for B omnidirectional chargers.

Some notions are presented to facilitate further analysis.

Definition 1 (Kuo et al. 2015) Given a finite set V , a real-valued function f on the set of subsets of V is called a submodular set function if and only if it satisfies one of the following two equivalent conditions.

1. $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$, $\forall A, B \subseteq V$;
2. $f(A \cup \{v\}) - f(A) \geq f(B \cup \{v\}) - f(B)$, $\forall A \subseteq B \subseteq V$ and $v \in V \setminus B$.

With these definitions, the critical lemma is presented as follows.

Lemma 1 *Given a subset A' of the candidate position collection $\mathcal{P}$, define $f'(A') = \sum_{j=1}^N U \left(\sum_{s_i \in A'} \Pr(s_i, 2\pi, o_j, \phi_j) \right)$, then $f'(A')$ is a submodular set function.*

Solution for CIRCLE-R

As Lemma 1 shows, the approximation algorithm described in Algorithm 2 for CIRCLE-R that consists of four steps is designed. First, the area is divided into uniform regular hexagon cells and classifies them into different groups, which is called *region division* (Steps 1–2). Second, the profit of each candidate position in the same cell in the same group is set as its caused increment to the overall charging utility using a greedy algorithm, while zero profit to candidate positions in the remaining group is assigned (Step 4). This step is called as *profit assignment*. Third, the problem of finding a connected subgraph with maximum charging utility is converted to the problem of finding a Quota Steiner Tree (QST), called as *finding QST* (Steps 6–13). Finally, as the obtained QST may contain more than B vertices, a dynamic programming is used to find the best subtree with at most B vertices in the QST, called as *calculating the best subtree* (Step 14). Next, the detail for these four steps is introduced in the following four subsections.

Region Division

A region H is found in the Euclidean plane such that not only it is large enough to cover all the N devices and the M candidate positions but it also can be partitioned into uniform smaller regular hexagonal cells with side length of $l = \frac{1}{2}R_c$. As such, the chargers in a same small regular hexagonal cell can communicate with each other. To make no device be charged by the different cells in the same group, the number of interval cells of different cells in the same group should be at least I along the division line as the dashed lines as Fig. 2 shows, where $I = \left\lceil \frac{2D}{\sqrt{3}l} \right\rceil$. Then these cells are partitioned into K different groups

Wireless Charger Deployment with Communication Constraint, Fig. 2 An instance of region division

where $K = I^2 + 2I + 1$ such that in each group, the number of interval cells between adjacent cells is exactly I . Without loss of generality, R_c is set to be one to simplify the derivation process. For example, as shown in Fig. 2, $I = 1$ is obtained given that $D = \frac{\sqrt{3}}{4}R_c$ and obtain four groups as shown in four different colors. In particular, let P_a represent the candidate position set in the same group where $a \in \{1, \dots, K\}$ and cl_i represent the candidate position set in the i -th regular hexagonal cell.

Profit Assignment

At this step, a greedy algorithm is used to assign a profit $W^* : \mathcal{P} \rightarrow \mathbb{Z}_0^+$ for the candidate position set $\mathcal{P}$ as described in Algorithm 1. For all candidate positions in a fixed cell of some group, a vertex p^* is greedily picked that has the maximum marginal charging utility that is rounded down to an integer. Note that the rounding-down process is necessary for assigning profit at the next step of finding a QST. With each selected vertex, its profit $w^*(p^*)$ is set to be the gained marginal charging utility. This step is repeated until all the candidate positions of the same group have picked and, then, set the profit for the other candidate positions of other groups to zero. Note that the order of choosing cells in the same group for assigning profit does not matter, because any pair of chargers in two different cells in the same group would never charge the same device.

Algorithm 1: Greedy algorithm for profit assignment

Input: Candidate position set $\mathcal{P}$, device set O , cell group P_a

Output: Profit assignment function $W^* : \mathcal{P} \rightarrow \mathbb{Z}_0^+$

```

1 for All  $p \in \mathcal{P}$  do
2    $w^*(p) = 0$ ;
3 for All  $cl_i \in P_a$  do
4    $X \leftarrow \emptyset$ ;
5   while  $|cl_i| \neq 0$  do
6      $p^* \leftarrow$ 
7        $\arg \max_{p \in cl_i \setminus X} [f'(X \cup \{p\}) - f'(X)]$ ;
8        $w^*(p^*) \leftarrow [f'(X \cup \{p^*\}) - f'(X)]$ ;
9      $X \leftarrow X \cup \{p^*\}$ ;
9 Output the profit value  $w^*$  for each candidate position.
```

Finding Quota Steiner Tree

After calculating the new profit for all the candidate positions, this profit is used for running a Quota Steiner Tree algorithm to find a tree T^* of size at most $4B$ whose quota is at least $\frac{1}{K}(1 - \frac{1}{e})OPT$, where OPT is the optimal profit. First, the definition of the Quota Steiner Tree is presented.

Definition 2 Quota Steiner Tree (QST). Given an undirected graph $G = (V, E)$, a profit function $p : V \rightarrow \mathbb{Z}_0^+$ on the vertices, a cost function $c : E \rightarrow \mathbb{Z}_0^+$ on the edges, and an integer (quota) q . A Quota Steiner Tree is the subtree T that minimizes $\sum_{e \in E(T)} c(e)$, subject to $\sum_{v \in V(T)} p(v) \geq q$.

The Quota Steiner Tree algorithm based on Johnson et al. (2000) and Garg (2005) achieves 2-approximation ratio. Therefore, if there exists a tree with at most $2B$ vertices and its quota being at least $\frac{1}{K}(1 - \frac{1}{e})OPT$, then the algorithm based on Johnson et al. (2000) and Garg (2005) can be used to find a tree T^* of size at most $4B$ with the quota of at least $\frac{1}{K}(1 - \frac{1}{e})OPT$.

Calculating the Best Subtree

At the last step, a tree T^* of size at most $4B$ is found. To obtain a feasible tree $\bar{T}$ of size at most B , there should calculate the best subtree

$\bar{T}$ of size at most B which has the highest total profit. A dynamic programming is used, which can be solved in polynomial time, to calculate the best subtree. Formally, the following problem is given. Given a tree $T^* = (V^*, E^*)$ of $4B$ vertices, each vertex has a profit $W^* : V^* \rightarrow \mathbb{Z}_0^+$, and an integer B , find a subtree $\bar{T}$ of size B which maximizes the total profit $w^*(\bar{T}) = \sum_{v \in \bar{T}} w^*(v)$, this subtree $\bar{T}$ is called the best subtree of T^* . Let the tree T^* be rooted at an arbitrary vertex and T_v^* denote the subtree of T^* rooted at a vertex v . Some notations used in the recurrence formula for the dynamic programming are introduced. $F(v, i)$ represents the best solution of at most i vertices completely contained inside T_v^* . $G(v, i)$ represents the best solution of at most i vertices completely contained inside T_v^* such that v is a part of the solution. Thus, calculating the best subtree becomes calculating $F(\text{root}, B)$. Suppose the root has m children represented as $v_1, \dots, v_m$, the following recurrence formula is obtained.

$$\begin{aligned}
 F(\text{root}, B) &= \max\{ \max_{1 \leq j \leq m} \{G(v_j, B)\}, \\
 &\quad G(\text{root}, B)\}, \\
 G(\text{root}, B) &= w^*(\text{root}) \\
 &\quad + \sum_{z=1}^m \max_{t_z=B-1} \{ \sum_{1 \leq j \leq m} G(v_j, i_j) \},
 \end{aligned} \tag{4}$$

The expression of $F(\text{root}, B)$ indicates that the best subtree with size at most B may be contained in the subtree with root root or in the subtree with root being one of the children of root . In addition, $G(\text{root}, B)$ is the sum of the profit of the root and the optimal profit of the best subtree with size of $B - 1$ contained in root 's children vertices. By tracking the intermediate state of the dynamic program, the optimal candidate positions for placing chargers can be obtained.

Theoretical Analysis for CIRCLE-R

In this subsection, theoretical analysis of the approximation ratio for our algorithm of CIRCLE-R is presented.

Theorem 1 *Algorithm 2 achieves a constant approximation ratio of $\frac{1}{67.50D^2 + 58.46D + 12.66}$ where D is the charging radius of chargers. When $D \rightarrow \infty$, the approximation ratio approaches $\frac{1}{67.50D^2}$.*

Proof. The detailed proof is omitted here to save space. $\square$

Note that the algorithm proposed by Huang et al. (2015) for solving the budgeted connected sensor cover problem achieves $\frac{1}{12.66(8C^2 + 4\sqrt{2}C + 1)}$ - approximation ratio where C is the sensing radius of sensor, a counterpart of D in the considered scenario. This is the best result, for solving the problem of maximizing a submodular set function with connectivity constraint. Apparently, the achieved approximation ratio of the algorithm

Algorithm 2: Algorithm for choosing the placement positions

Input: Candidate position set $\mathcal{P}$, device set O , budget B
Output: Candidate position set T for placement

- 1 Use the same size of regular hexagon to divide plane H ;
- 2 Calculate the group number K , determine which group each candidate position belongs to;
- 3 **for each group** P_a **do**
- 4 Call the greedy algorithm described in Algorithm 1 to assign the profit to each candidate position;
- 5 $\text{left} \leftarrow 0, \text{right} \leftarrow w^*(\mathcal{P})$;
- 6 **while** $\text{left} + 1 \neq \text{right}$ **do**
- 7 $\text{OPT}_{\text{GUESS}} \leftarrow \text{left} + (\text{right} - \text{left})/2$;
- 8 Call the 2-approximation algorithm based on Johnson et al. (2000) and Garg (2005) for the QST problem with the instance $(\mathcal{P}, w^*)$ as the input to obtain a tree T^* with quota at least $\text{OPT}_{\text{GUESS}}$;
- 9 **if** $|T^*| \leq 4B$ **then**
- 10 $T^* \leftarrow T^*$;
- 11 $\text{left} \leftarrow \text{OPT}_{\text{GUESS}}$;
- 12 **else**
- 13 $\text{right} \leftarrow \text{OPT}_{\text{GUESS}}$;
- 14 Use a dynamic program to find the best subtree $\bar{T}$ of the tree T^* ;

improves at least 1.5 times compared with the algorithm in Huang et al. (2015).

Approximation Algorithm for CIRCLE

In this section, based on the analysis to CIRCLE-R, the original CIRCLE problem is considered that takes into consideration the directional charging pattern of chargers and the budget constraint for each candidate position (that is, each candidate position is allowed to place more than one chargers while not exceeding a given budget) compared with CIRCLE-R.

Problem Formulation for CIRCLE Without Budget Constraint for Each Candidate Position

After choosing the best B candidate positions for placing chargers in CIRCLE-R, CIRCLE problem becomes choosing the best orientation of each charger to maximize the charging utility. Therefore, CIRCLE problem can be defined as follows.

$$\begin{aligned}
 (\text{P3}) \quad & \max \sum_{j=1}^N U \left(\sum_{s_i \in T} \Pr(s_i, \theta_i, o_j, \phi_j) \right) \\
 \text{s.t.} \quad & \theta_i \in [0, 2\pi)
 \end{aligned} \tag{5}$$

where $f^*(T, \theta_i) = \sum_{j=1}^N U \left(\sum_{s_i \in T} \Pr(s_i, \theta_i, o_j, \phi_j) \right)$ is the overall charging utility considering the orientations of chargers.

Solution for CIRCLE Without Budget Constraint for Each Candidate Position

Candidate Orientation Angle Extraction

The following definition is given to facilitate further analysis.

Definition 3 (dominant coverage set) Given a set of devices $\mathcal{O}_i^1$ covered by a charger s_i with some orientation, if there does not exist another set of devices $\mathcal{O}_i^2$ covered by the charger s_i with

Algorithm 3: Algorithm for candidate orientation angle extraction

Input: Charger position set T , device set O , charging angle A_s

Output: Collection of sets of charger orientation angles A^θ

```

1 for all  $T_i \in T$  do
2   Find the subset of devices  $O_i \subseteq O$  that satisfy
    $Distance(o_i, T_i) \leq D$  for each device  $o_i$  in set  $O_i$ ;
3   Rotate the charger with charging angle  $A_s$ 
   anticlockwise to cover the devices in  $O_i$  one by
   one until there is some covered device going to
   be uncovered. During the rotating process, if
   the rotated angle is larger than  $2\pi$ , then
   terminate;
4   Add the current covered set of devices to the
   collection of dominant coverage sets and add
   the current orientation angle  $\theta_i^1$  to the set  $A_i^\theta$ ;
5   Rotate the charger anticlockwise until a new
   device in  $O_i$  is included in the covered set. If
   the rotated angle is larger than  $2\pi$ , then
   terminate. If not, goto Line 3;
6    $A^\theta \leftarrow A^\theta \cup \{A_i^\theta\}$ ;
7 Output the collection of sets  $A^\theta$ .
```

some other orientation such that $\mathcal{O}_i^1 \subset \mathcal{O}_i^2$, then $\mathcal{O}_i^1$ is a dominant coverage set.

As any possible covered set of devices is a subset of a certain dominant coverage set, rather than considering all possible orientation angles of a charger in a candidate position, there only need to consider those orientation angles, called candidate orientation angles, that cover the dominant coverage sets of devices. The algorithm for candidate orientation angle extraction is described in Algorithm 3.

Selecting Orientation Angle

After candidate orientation angle extraction, a possible orientation angle set A_i^θ for each charger T_i is obtained. At this step, a greedy algorithm is used to find the best orientation angle θ_i for charger s_i that maximizes the increased charging utility when adding T_i to the charger set $\{T_1 \cup \dots \cup T_{i-1}\}$. The algorithm is described in Algorithm 4. For each charger, Algorithm 4 greedily adds the orientation θ_i to set θ such that the increment of the function f^* is maximized.

Algorithm 4: Greedy algorithm for selecting best orientation angle for each charger

Input: Charger position set T , device set O , charging angle A_s

Output: Orientation angle set θ for all chargers

- 1 Call Algorithm 3 with the instance (T, O, A_s) as the input to obtain the collection of sets of charger orientation angles A_i^θ ;
- 2 $\theta \leftarrow \emptyset$; $X \leftarrow \emptyset$;
- 3 **for all** $T_i \in T$ **do**
- 4 $\theta_i \leftarrow \arg \max_{A_{ij}^\theta \in A_i^\theta} f^*(X \cup \{T_i\}, A_{ij}^\theta)$
 $- f^*(X, \theta_{i-1})$;
- 5 $X \leftarrow X \cup \{T_i\}$;
- 6 $\theta \leftarrow \theta \cup \{\theta_i\}$;
- 7 **Output** best orientation angle set θ .

Algorithm 5: General algorithm for CIRCLE

Input: Candidate position set $\mathcal{P}$, device set O , budget B , and charging angle A_s

Output: Charger position set $\mathcal{T}$ and best orientation angle set Θ^*

- 1 For each candidate position p_i with budget constraint l_{p_i} , replace it with l_{p_i} candidate positions each of which is allowed to place only one charger, and thus construct a new candidate position set $\mathbb{P}$;
- 2 Call Algorithm 2 with the instance $(\mathbb{P}, O, B)$ as the input to choose the placement position set $\mathcal{T}$ of size at most B ;
- 3 Call Algorithm 4 with the instance $(\mathcal{T}, O, A_s)$ as the input to obtain the best orientation angle set Θ^* ;
- 4 **Output** $\mathcal{T}$ and Θ^* .

Solution for CIRCLE and Theoretical Analysis
Problem Redefinition

In this subsection, the more general situation is considered. Before describing the algorithm, CIRCLE problem is redefined as follows.

$$\begin{aligned}
 (\mathbf{P4}) \quad & \max \sum_{j=1}^N U \left(\sum_{s_i \in T} \sum_{\theta_i \in \Theta_i} \right. \\
 & \left. \Pr(s_i, \theta_i, o_j, \phi_j) \right) \\
 \text{s.t.} \quad & \theta_i \in [0, 2\pi) \quad \text{and} \quad \Theta_i \subseteq A_i^\theta \quad (6)
 \end{aligned}$$

Solution for CIRCLE

The general algorithm is illustrated in Algorithm 5. First, l_{p_i} same positions are generated

for each candidate position p_i in the candidate position set; the newly generated set is denoted as new candidate position set $\mathbb{P}$ (step 1). Second, Algorithm 2 is used on the new candidate position set $\mathbb{P}$ to choose the placement position (Step 2). Third, Algorithm 4 is used to select the best orientation angle for each placement position (Step 3).

Theoretical Analysis for CIRCLE

Theoretical analysis of the approximation ratio for the proposed algorithm described in Algorithm 5 for CIRCLE is given in this subsection.

Theorem 2 *Algorithm 5 achieves a constant approximation ratio of $\frac{A_s}{2\pi(67.50D^2 + 58.46D + 12.66)}$.*

Definitions

Wireless communication is the information transfer between two or more points that are not connected by an electrical conductor. The information is transmitted via the propagation of electromagnetic wave signals in free space. Wireless communication technologies can be incorporated in data centers (DCs) to overcome the cabling complexity and hotspots problems encountered by conventional wired data centers.

Historical Background

A data center is a physical or virtual centralized repository for storing, managing, and disseminating data. The concept of DC network (DCN) refers to the network infrastructure that provides intra- and inter-DC communications, which has received much attention in network research field. Generally, when designing a DCN, the designers need to consider several factors including scalability, latency, reliability, cost, and other practical details (Mudigonda et al. 2011).

Most existing DCNs rely on wired networking technologies, i.e., the communication service is implemented by using copper cables or fiber optics. The design and implement of wired DCNs face some inevitable problems, which lead to unsatisfactory network performance. Since the traffic patterns of DCN applications are difficult to predict, the conventional tree-based topology in wired DCNs often encounters the hotspot problem and flow congestion, especially when a burst of traffic occurs. In order to adapt to as many traffic patterns as possible, the cables and switches have to be over-deployed at high cost when designing the network (Huang et al. 2013). Moreover, when adding new servers to the network, considerable rewiring of the existing devices may be required, which increases the cabling complexity. The cable bundles behind the racks also cause problems of inefficient cooling and high maintenance cost. Although researchers have been working on new architectures (e.g., fat tree, DCell, BCube) in wired DCNs, the problems of hotspot and cabling complexity remain unsolved.

Foundations

Due to the limitations and problems in the existing wired DCNs, researchers have been working on incorporating wireless communication technologies in DCNs. Up to now, 60 GHz radio frequency (RF) and free space optics (FSO) are two candidate technologies which are mostly discussed.

60 GHz RF Technology

RF communication operates in the band of millimeter wave (mmWave) and benefits from the high frequency and large spectrum. Ramachandran et al. first introduce the idea of utilizing 60 GHz technology in DCNs (Ramachandran et al. 2008). It is pointed out that the radios in the license-free 60 GHz range give them operational advantages over others for providing link connectivity in data centers. It is suggested that building indirect LOS links by using reflectors for intra-rack communications,

and creating LOS, indirect LOS of multi-hop links for inter-rack communications.

In order to enhance the performance of conventional DCNs, flyways are designed to add additional on-demand links to wired DCNs (Kandula et al. 2009). The flyways can be wired switches or wireless transceivers. The use of wireless flyways can reduce the completion time of the demands and hence improve the performance of the network. Adopting 60 GHz wireless technology in wireless flyways can speed up DCN applications to some extent (Halperin et al. 2011).

When it comes to the topology design, it is possible to incorporate 60 GHz technology in the typical DCN topologies, i.e., hierarchical and fat-tree architectures, and implement direct LOS wireless links among the servers and switches (Prakash 2014). In addition to emulating well-known topologies, some researchers also work on designing new topologies for wireless DCNs. A novel DCN topology can be modeled as a mesh of Cayley graphs (CG). A semi-regular mesh topology is implemented by incorporating 60 GHz wireless transceivers and switching logic within each server node and arranging them in cylindrical racks. In this novel design, both the physical and the logical topologies are different from the typical wired topologies. Moreover, Cayley DCN can perform better in packet delivery latency and failure tolerance when compared to fat-tree DCN (Shin et al. 2012).

FSO Technology

FSO communication, also known as optical wireless communication (OWC), combines the advantages of both wireless and optical communication systems. FSO modulates light beam which propagates wirelessly from one point to another [8]. Light-emitting diodes (LEDs) and laser diodes can act as the light source at the transmitter in an FSO link.

The design and applications of power smart FSO links in DCNs have been widely discussed. In order to improve the mobility and modularity, containerized DCNs can be used where servers and other devices are arranged in a container. FireFly offers an inter-rack network solution for

wireless DCN design. The FSO transceivers are arranged on the top of racks (ToRs). Moreover, all FSO links are reconfigurable by using switchable mirrors (SMs) or Galvo mirrors (GMs). SMs can be switched to mirror or transparent states, and GMs can be rotated within a limited a range (Hamedazimi et al. 2014). In this way, the light beam in an FSO link can be deflected in the direction as designed. However, the links are limited to unicast. A new switching element, namely, tri-state switching element (T-SE), has three optional states are reflective, transmissive, and splitting state. When a T-SE is in the splitting state, the incident beam can be split into several copies and hence it realizes multicast (Hamza et al. 2016).

Challenges in Wireless DCNs

As mentioned above, the design of a robust DCN has to meet some requirements, e.g., network capacities, data transmission rate, interference, cooling efficiency, power consumption, maintenance cost, etc. The utilization of wireless technologies in DCNs also faces some challenges in meeting the requirements. For 60 GHz technology, the practical bandwidth is lower. Appropriate bandwidth allocation and interferences alleviation are required. In wireless DCN utilizing FSO technology, as all the point-to-point FSO links need accurate alignment, the choice of light source and the vibration of the light beam have to be carefully considered (Turner 2010). Moreover, using artificial light for the illumination of DCs may cause interference of the FSO links.

Key Applications

Wireless technologies can be incorporated in data centers to build wireless DCNs which can overcome the limitation of wired DCNs.

Wireless Edge Caching

Zhiwen Hu, Zijie Zheng, and Lingyang Song
School of Electronics Engineering and Computer
Science, Peking University, Beijing, China

Synonyms

[Edge caching](#); [Mobile caching](#); [Mobile content delivery](#); [Wireless caching](#)

Definition

Wireless edge caching is the technique that distributes duplicate contents from the original Internet server to the cache-enabled devices in wireless networks. These devices often refer to the gateways in the core networks (CNs) or the base stations in the radio access networks (RANs), and in some cases, cache-enabled mobile devices (such as cell phones) can also be taken into account. With wireless edge caching, mobile users are able to obtain the desired contents directly from those nodes instead of tracing back to the original Internet server. Both the access delay of the mobile users and the backhaul traffic of the wireless networks can be reduced.

Historical Background

With the proliferation of the Internet in the late 1990s, popular web services started to face the

problem of congestion and bottlenecks due to frequent demands from users (Pathan and Buyya 2007). Content delivery network (CDN) was then proposed to deal with this problem by replicating the original contents and caching them into other servers with different geographical locations (Douglass and Kaashoek 2001). CDN cache servers are also called as edge servers, since they are usually closer to the end users who require the contents. Correspondingly, CDNs have constituted the most important part of *edge caching* since then.

The relevant concept, wireless edge caching, comes from the demand for rich multimedia services over wireless networks in recent years (Wang et al. 2014). Mobile users access the Internet through the RANs and the CNs, where the lengths of the intermediate links are longer than that of the links of traditional wired users. Thanks to the evolving 4G and 5G systems, the RANs and the CNs are expected to be endowed with the ability to cache contents (Ramanan et al. 2013). Along with the cache-enabled user devices, all the related nodes in the wireless networks can be seen as edge caching servers, which forms the concept of *wireless edge caching*.

Foundations

Caching is the technique that essentially reduces duplicated transmissions in the system with the cost of additional caching storages and computing resources. Such trade-off is profitable as long as the reduction of duplicated transmissions is valuable enough to counteract all the costs (Erman et al. 2011). Due to the recent development of storage techniques, the cost of deploying caching storages becomes more and more negligible. Based on the long-tail property of the distribution of popularity of contents, only a small proportion of popular contents are requested by a large portion of mobile users, which makes caching a promising way to deal with duplicated transmissions. From the view of the wireless network operator (WNO) who runs the devices of

Wireless Edge Caching,
Fig. 1 The basic
architecture of wireless
communication networks

the wireless network, wireless edge caching can avoid unnecessary usages of bandwidth-limited links in the wireless network and thus reduces the probability of congestion during rush hours. From the view of the mobile users who aim to download their desired contents, wireless edge caching is also able to averagely bring lower access latency and improve user experience.

The basic architecture of a wireless communication network has a multilevel topology, as illustrated in Fig. 1. To connect to the Internet, user terminals (UTs) in the user network (UN) layer have to rely on the CNs and the RANs, which contains the devices managed by the WNO. The CN mainly consists of different kinds of gateways, and the RAN mainly consists of macro base stations (MBBs) and small base stations (SBSs). A practical structure of a wireless network could be more complicated, but the basic idea remains the same. As CDNs can provide caching services for mobile users with the assistance of CDN servers, other network nodes in the CN, the RAN, and the UN layers can also be applied as caching storages to move the replicate contents closer to the edge of the wireless networks. Caching in the CN, the RAN, and the UN layers can be considered as the three major aspects of wireless edge caching. While CN caching has the advantage of large caching storages and high hit rate, RAN caching

leads to much lower latency and also saves the backhaul bandwidth of the RAN. With the help of device-to-device (D2D) and vehicle-to-vehicle (V2V) transmissions, UT caching brings the contents closest to end users. The system would be quite efficient by utilizing hybrid caching which includes all the caching layers in wireless edge caching along with wired edge caching.

Wireless edge caching strategies can be generally classified into two categories based on the knowledge of content popularity, which are *reactive caching* and *proactive caching*. Reactive caching refers to the caching schemes in which the cache-enabled devices are not aware of the popularity of the contents. Each device can only adjust its caching storage based on the local information (i.e., the history of the requests sent to this device) in a reactive manner. Exemplary reactive caching schemes include First In First Out (FIFO), Least Recently Used (LRU), and Least Frequently Used (LFU) (Lee et al. 2001). Proactive caching, however, refers to the caching schemes in which the cache-enabled devices are aware of the popularity of contents based on some centralized estimations and predictions. The contents are allocated into the caching storages by the WNO in a proactive manner. With enough estimation and prediction accuracy, proactive caching can achieve a better performance compared with reactive caching

(Baştuğ et al. 2014). Therefore, the recent rapid development of machine learning techniques is able to improve the efficiency of proactive caching. Another noticeable aspect of proactive caching is that the interest-relevant groups (e.g., WNOs, content providers, and mobile users) may influence the caching results with game interaction (Hu et al. 2016), which is not a vital concern in reactive caching.

From another perspective, wireless edge caching strategies can also be classified into *content-aware solutions* and *non-content-aware solutions*. In content-aware solutions, each content has a unique identity to distinguish from each other in the caching storages. Each caching device is aware of whether a specific content is cached in its storage. In non-content-aware solutions, caching devices cache the contents based on chunks, packets, flows, or even bytes. Contents are no longer stored as whole entities in the storages of those devices. Current deployed CN caching solutions include both content-aware caching and non-content-aware caching (Woo et al. 2013). Since the method being applied is very much alike with that of the traditional CDN caching, a network with CN caching is usually called as a mobile content delivery network (mobile CDN). RAN caching, however, is not ready to apply content-aware caching given the current hardware in the 4G system, because the RANs only establish tunnels between the UTs and the CNs and are not content-aware. Nevertheless, the concept of information-centric networking (ICN) architecture (Zhang et al. 2013) for the future Internet is a promising technique to enable content-aware RAN caching.

Key Applications

Wireless edge caching is a useful design consideration of establishing practical wireless networks.

Wireless Fading Channel Model for 5G and Future

Jianhua Zhang
Beijing University of Posts and
Telecommunications, Beijing, China

Synonyms

Channel impulse response (CIR); Wireless communication

Definition

The *communication channel* is a kind of physical medium or pathway such as air, water, and vacuum which can be used to carry information from a transmitter to its receiver. According to electromagnetic radiation theory, a *wireless channel* refers to the wave conveying a radio frequency (RF) signal between a source and its receiver in space. Thus, in wireless communication systems, the propagation characteristics of a *wireless channel* directly determine the performance limit of the wireless communication system. *Wireless channel model* is applying physical or mathematical methods to describe its fading characteristics and regenerate channel impulse response (CIR). While due to the complex reflection, diffraction, and scattering of the electromagnetic wave in real environments, an accurate and efficient channel model is crucial to the research of novel transmission techniques, the evaluation of standardization proposals, and the actual deployment of wireless system etc.

Historical Background

Since J. C. Maxwell forecasted the existence of the electromagnetic wave in 1865 and H. R. Hertz experimentally proved in 1887, wireless mobile communication system has experienced rapid development, especially, terrestrial mobile communication from the first generation (1G) in 1980s to the fourth generation (4G) around 2010, and fifth generation (5G) is expected around 2020. Wireless channel models have been widely studied over the world since then; a lot of research activities were carried out based on different requirements (Zhang 2012).

The initial research of wireless channel models can be traced back to 1940s, when Bell Labs gave the Ricean statistic model, which defines the amplitude fading distribution of a narrowband channel with a line of sight (LoS) path (Rice 1944). In the 1950s, Lincoln Laboratory proposed a time-frequency two-dimensional statistic model in order to describe

the resolvable multipath in delay domain. That is the early concept of tap-delay-line (TDL) model for second- (2G) and third-generation (3G) mobile communication system research. From 1970s, the field measurement campaigns were carried on by the sounder either by single pulse scheme or sequence correlation scheme (Cox 1977; Turin et al. 1972). Many classical empirical models appeared, for example, Egli, Okumura, Hata, Walfisch, and Bertoni models. In particular, some organizations and institutions have also defined their standardized channel models, i.e., Global System for Mobile communications (GSM) 05.05 and International Telecommunications Union-Radio (ITU-R) M. 1225 for 2G and 3G radio transmission techniques (RTT) research and development. GSM 05.05 is specified by European Telecommunication Standard Institute (ETSI) which covers Rural Area (6 taps), Hilly Terrain (12 taps), and Typical Urban (12 taps) cases (ETSI EN 300 910 2000). ITU-R M. 1225 is defined for IMT-2000 (3G) which includes TDL models for Indoor office, Outdoor to indoor, and Pedestrian, Vehicular cases (ITU-R M.1225 1997).

Foschini and Gans (1998) and Telatar (1999) discovered that multiple-input multiple-output (MIMO) can provide remarkable spectral efficiency; the channel model is naturally expanded to space-time-frequency three dimensions in order to support MIMO study. Thus, double-directional model is proposed which combines the angle of departure (AOD) from transmitter with the angle of arrival (AOA) to receiver (Molisch et al. 2006). Moreover, cluster is revolutionarily introduced into modeling in order to describe the multipath components (MPCs) more accurately with low complexity (Saleh and Valenzuela 1987). Based on the above progress, geometry-based stochastic channel model (GBSM) was born and has been adopted by standardization organizations, i.e., spatial channel model (SCM) of 3rd generation partnership program (3GPP) and ITU-R M.2135 for IMT-Advanced evaluation.

To meet 5G new requirements, including 3D MIMO, millimeter wave (MM), and high speed, GBSM model is continuously evolved into cover

elevation domain, i.e., 3D MIMO channel model (Zhang et al. 2017a) and standardized into 3GPP TR 36.873 (3GPP TR 36.873 V1.0.0 n.d.). New features for millimeter (mm) wave is studied (Rappaport et al. 2017; Zhang et al. 2017b) and standardized into 3GPP 38.900/901 (3GPP TR 38.900 2016; 3GPP TR 38.901 2017). ITU-R has also launched the draft group for IMT-2020 (5G) channel model since 2016 and its work is nearly finished (ITU-R M.2412 2017). Thus, 5G channel model is defined and issued after October 2017 in order to support the 5G system design and application before 2020.

Foundations

It is known that versatile objects exist in the real environments, like glass windows, concrete buildings, plants, moving cars, etc. The radio waves may be reflected, scattered or diffracted, arrive at the receiver through different paths as shown in Fig. 1. Thus the received signal is the sum of multiple radio waves with different phases and delays. Consequently, the transmitted signal experiences dramatic variation when going through the radio channel and such fading is plotted in Fig. 2 as the red line.

For simplicity, this fading is classified to *large-scale fading* and *small-scale fading*. Large-scale fading in Fig. 2 as blue line describes the average channel gain over a distance of tens to a few hundred wavelengths. It is important for coverage prediction and interference analysis

of a radio system. Typical large-scale fading is modeled into *Path loss* and *shadow fading*. Path loss in Fig. 2 as black line is the reduction in power density of a radio wave as it propagates through the distance. Shadow fading is caused by large terrain features between the transmitter and receiver. As for the small-scale fading, it describes the signal variation over a short distance scale, e.g., fractions of wavelengths. Small-scale fading determines the performance of air interface technologies. And the *small-scale fading* parameters, including delay spread, AoD and AoA, Doppler frequency, and complex magnitude of polarization, are acquired by first using a multidimensional joint parameter estimation algorithm from the measured data.

In order to describe the channel fading properties and regenerate CIR as red line in Fig. 2 accurately and efficiently, there are various channel model methodologies. Taking the MIMO channel model for example in Fig. 3, they can be classified into three categories, i.e., geometrical-based stochastic model, correlation-based model, and deterministic model. For geometry-based stochastic model, response of MPCs on the different elements of antenna array are geometrically calculated while delay spread, AoD and AoA, Doppler frequency, and complex magnitude of polarization are determined by empirical distribution. Because the model can reflect the real environment with low complexity, it is popular in standards, including ITU-R IMT-2020, WINNER+, 3GPP 36.873, 3GPP 38.900/901, and COST2100. The

Deterministic model	Ray-tracing method	
	Hybrid model	METIS map-based channel model

correlation-based channel model, especially Kronecker model, is well used in analyzing MIMO performance theoretically. Its CIR is expressed by channel correlation matrix which includes transmitting and receiving antennas' correlation parameters and channel variance. In terms of deterministic channel model, solution of Maxwell' s equations are used to determine the accurate CIR of a location by detailed geographic information. It is highly complex and relies on the precision of the geographic information. Recently, hybrid model and map-based model

from METIS are proposed for mm wave band channel model.

Key Applications

The growing research in the discussion of 5G wireless communications system has aroused the attention of the whole world since the successful commercialization of 4G. As 3GPP has preliminarily planned to open 5G new radio (NR) standardization process at the end of 2015;

it becomes urgent to establish related criterion for 5G NR evaluation. Compared with previous mobile communication systems like 3G or 4G, 5G and the beyond has been expected to include a bunch of new requirements, applications, and scenarios, e.g., massive and 3D MIMO, high frequency (millimeter wave), machine-to-machine, device-to-device, vehicle-to-vehicle, unmanned drone and high speed trains, satellite, etc.

Future Directions

Supporting the tremendously high data rates and constantly increasing new applications is the main task of 5G and future wireless communication system. To meet the huge demands, IMT-2020 is expected to offer the user experienced data rate to 100Mbps and peak data rate to 20Gbps. Furthermore, the vision of IMT-2020 presents the convergence of wireless communication, Internet, Internet of Things (IoT), and Machine-type Communication (MTC), which also brings increasing pressure to channel model research. Here remains some of the promising directions and open issues.

At present, mm wave and THz frequencies are now researched by major research institutions and industry. However, mm wave channels can be influenced by some fundamentally different propagation effects, such as atmospheric absorption, fog, rain, and shadows of human bodies and other material objects (Callum et al. 2017). Moreover, expensive measurement equipment and limited measurement data lead to that we can't master the comprehensive properties of mm wave and THz channel. Thus, we still need to put a lot of effort in order to explore so many bands of mm wave and THz, like cluster sparsity, spatial information, and suitable modeling methodology.

Due to the increased antenna number, larger bandwidth, and versatile complexity scenarios in 5G and future communication system, the measurement data reveals big volume feature. Thus, it is very natural that data mining schemes can be used to replace the conventional statistic schemes in channel characteristic analysis and some initial work already presented in (Ma et al.

2017). Moreover, artificial intelligent (AI) is also an intelligence exhibited by machines, which can find out the internal rules from data sets and then transform the rules to suitable models with learned parameters. By utilizing AI methods, we can cope with tasks such as feature extraction, classification, and prediction from the measurement data. Then we can apply them to analyze and reconstruct the real wireless channel more efficiently (Zhang 2016).

Wireless connectivity is an essential ingredient to Internet of Things (IoT), and 5G is a potential enabling technology bringing about spectrum, lower-cost connectivity to the IoT. But due to the rapidly changing propagation conditions that are typically found in IoT communication environments, the Doppler shift effects and the nonstationary characteristics of the wireless channel become exacerbated. Therefore, proper channel models are needed to provide insights into the physics of IoT radio reception.

Wireless Group Authentication

Anxi Wang
School of Computer and Software, Nanjing
University of Information Science and
Technology, Nanjing, China

Synonyms

Group authentication; Secret sharing

Definitions

Entities in wireless networks are always organized into group for network managers'

convenience. Group authentication is the entity identification strategy based on the identities or features of the wireless entities. Owing to the group structure, group authentication is very suitable for wireless networks. In addition, group authentication is one of the most important technologies for wireless communication in that network.

Historical Background

Group authentication is developed to provide better security for group-oriented network. In a wireless group-oriented network, there are multiple entities wanting to form a private network to exchange messages. In order to protect the exchanged messages, every entity in the network should authenticate others. According to the centralized authentication (CA) server's participation, group authentication schemes can be divided into three types: CA-centric type, entity-centric type, and CA-aided type.

In the CA-centric type, the CA takes the role of communicating with entities and authenticating entities. In 2006, Bhakti et al. (2007) proposed to adopt extensible authentication protocol (EAP) in the IEEE 802.1x Standard (Craig et al. 2002) for wireless ad hoc network. EAP has been thought to be the representation of CA-centric group authentication scheme.

In the entity-centric type, each entity authenticates group members. If there are n members in one group, each entity authenticates $(n - 1)$ times by applying conventional authentication scheme. The $O(n)$ complexity is the bottleneck for the widespread use of this type of group authentication schemes.

In 2013, Lein Harn (2013) proposed a secret sharing-based group authentication scheme, which authenticates all users at once. This group authentication scheme is based on an n -th order polynomial function, which was first applied to the field of cryptography by Shamir in 1979. This group authentication is named CA-aided type, which combines the advantages of the above two authentication methods. However, this group

authentication is unable to resist collusion attacks by more than n entities.

Many security and overhead issues have been found in these group authentication schemes. In the CA-centric type, network participants should fully trust the CA. The security and privacy may be leaked by the malicious CA or malicious attacker who attacks the CA. In the entity-centric type, the communication and computation cost to each entity is very huge. The heavy cost may badly affect the main functions of the wireless networks. In the CA-aided type, collusion attack is the main security risk. In addition, the secret shared among each entity takes up a lot of network bandwidth. How to overcome the security and overhead issues has become the top priority for promoting group authentication schemes.

Foundations

There are a series of group authentication methods in wireless networks. According to whether the protocol is based on encryption technology, it is divided into the following four types: key pre-distribution scheme, broadcast scheme, key update scheme, and secret sharing-based scheme.

Key pre-distribution-based scheme Many key distribution schemes are designed to provide secure communication among communication entities. Key pre-distribution scheme (Chan et al. 2003) is the most accepted key distribution method in wireless networks (Bechkit et al. 2013). The key generators provide secret keys to others before the network was formed. The key receivers are thought to be authenticated by the key generator. In wireless networks, the key generator and key receivers form a message exchange group. However, there are some drawback of the scheme, which cannot be ignored. Firstly, the group is fixed after it is generated. If the number of members in the group changes, the group authentication is also changed. Secondly, the authentication information increases linearly with increasing

number of members in the group. This is a major challenge to a user's storage and update capability. Thirdly, even if the group is accidentally attacked, the intragroup secret key cannot be changed.

Broadcast-based scheme Each entity sends a group key to a selected set of entities (Ren et al. 2009). In the broadcast scheme, which is based on a symmetric key, the sender has fixed authority to determine the set of receivers. In this case, the size of key has a minimum value (Perrig et al. 2005). In addition, safety is only guaranteed among a limited number of users. In the public key broadcast scheme, the key size problem can be avoided, but the threshold number of bad users is still set for safety. Note that the size of the ciphertext depends on the number of users, so it may be large in a large group. Therefore, the broadcast-based scheme is more flexible than key pre-distribution-based scheme.

Key update-based scheme This type is applicable to the case where the number of entities in the network changes during communication of the network (Wang et al. 2006). When an entity leaves the network, the network manager needs to rerun the authentication phase. In this method, the two questions must be considered. The operation is performed by the network manager, and the key is updated frequently. At the same time, whenever the number of entities changes, the authentication operation is repeated, which is unrealistic for actual wireless networks. Note that the key update-based schemes are stronger than the key pre-distribution-based schemes and the broadcast-based schemes.

Secret sharing-based scheme In addition to encryption certification, group authentication schemes have also been proposed based on different mathematical tools. After secret sharing schemes were first proposed by Shamir (1979), the scheme was applied to group authentication. In 2010, Harn (2013) proposed a basic t -secure m -user n -group authentication scheme($t; m; n$). The $(t; m; n)$ scheme can greatly reduce the user's computational cost. In 2015, Miao

et al. (Fuyou et al. 2015) found that the shared data in Harn's scheme is not bound to each other and introduced the notion of a randomized component (RC) to bind share data with all users and to protect the share data from being exposed to the outside without computational assumptions. Several researchers have designed new schemes to overcome the upper limit of t (Lin et al. 2012). However, the upper limit still exists in secret sharing schemes.

Key Application

Wireless group authentication scheme provides the secure communication among entities when they exchange message in wireless networks. In addition, when the authentication scheme accomplished, a group secret key can be generated for data protection (Ateniese et al. 1998; Lai et al. 2013). Group authentication schemes still should be improved to achieve high availability with high security.

Definitions

In wireless networks, jamming attacks disrupt the legitimate communication between two nodes using interference signals. As a result, a channel between a sender and a receiver is blocked.

Historical Background

Over the last decades, wireless communications have been used widely to exchange data between multiple devices. In a wireless communication system, both a transmitter and a receiver share critical information during the transmission time. This makes the wireless channels to be subject to challenging aspects, such as noise and interference. Additionally, there are security concerns associated with wireless communication systems due to open nature of wireless networks, and the limitation of the power and computation capability of each device. Jamming attacks aim to target the channel of wireless communication systems and to prevent both a sender and a receiver from sharing data.

A jammer aims to prevent a legitimate sender and receiver from sending and receiving messages. He can simply emit noise signal to make the channel busy such that a sender is not able to transmit data. Also, a jammer can send junk data to a receiver. As a result, a receiver cannot recover the received message correctly. Both nonreactive and reactive jammers are considered as the most popular types of jamming attacks. A nonreactive jammer has no knowledge about the channel usage status. On the other hand, a reactive jammer senses the channel before it starts jamming. If the channel is idle, the jammer stays quiet. If a jammer detects transmission on the channel between a sender and a receiver, it starts emitting noise signal on the channel.

In fact, it is important to make the wireless communication between a sender and a receiver reliable by developing new schemes to mitigate the effects of jamming attacks. Frequency-hopping spread spectrum (FHSS) and direct-sequence spread spectrum (DSSS) are examples of spread spectrum techniques that have been widely used to defend against jamming attacks for wireless communication systems (e.g., Grover et al. 2014; Liu et al. 2010b). Traditional FHSS and DSSS assume that the sender and the receiver share the same secret key to encode messages. The shared secret key enables the communicators to generate the same frequency-hopping patterns

or spreading code sequences. Therefore, if a jammer knows the secret key, then he can jam the communication channel by using the same frequency-hopping patterns and spreading code (Pöpper et al. 2009).

Research work has been done to overcome the concern of establishing jamming-resilient communication with a pre-shared secret key. Strasser et al. proposed an anti-jamming system based on an uncoordinated frequency hopping (UFH), which enables two wireless devices to establish a secret key during the transmission time in the presence of a jammer (Strasser et al. 2008). Pöpper et al. created a scheme called uncoordinated direct-sequence spread spectrum (UDSSS), which can remove the requirement of a shared secret key for DSSS systems (Pöpper et al. 2009), and a sender always selects random spreading code sequences from a public set to spread a message.

Randomized Differential DSSS (RD-DSSS) is another anti-jamming system developed to remove the requirement of a shared secret key. In RD-DSSS, both a sender and a receiver share public spreading code sequences. A sender spreads a message based on a chosen index code, which is appended to the end of a spread message to facilitate the decoding at the receiver (Liu et al. 2010b). Liu et al. developed a new scheme, named Delayed Seed-Disclosure DSSS (DSD-DSSS), against jamming attacks with no need of sharing a secret key. They achieve anti-jamming wireless communication by generating a random seed, which can be used to generate random code sequences to spread each message. To disclose a seed, a sender spreads a seed using publicly known code sequence set and positions it to the end of a spreading message (Liu et al. 2010a).

Background Information on FHSS

FHSS transmits the wireless signal over multiple channels to avoid interference. Specifically, the transmitter and the receiver hop from one frequency to another based on a shared frequency-hopping pattern generated by a

pseudo-noise (PN) generator. The transmitter multiplies the transmit signal with a carrier of different frequencies, and the receiver searches signals according to the corresponding frequencies.

A receiver must be able to align with the signal sent by the transmitter. Toward this goal, both the transmitter and the receiver may stay on a certain channel without hopping until they hear from each other, or the transmitter may stay on a certain channel, and the receiver searches over different channels until it discovers the signal from the transmitter. Once the signal alignment is done, the transmitter and the receiver can start hopping over different frequencies according to the shared frequency-hopping pattern. Strasser et al. proposed a new way for signal alignment by using uncoordinated hopping and public key cryptography (Strasser et al. 2008). The basic idea is to let the transmitter and receiver randomly hop over different frequencies but at different hopping rates. Once the communicators are on the same channel, the transmitter sends the receiver a secret value that is encrypted by the public key of the receiver, who will decrypt this value using the corresponding private key. The transmitter and the receiver then generate shared hopping pattern based on the secret value. The advantage of this method is that the transmitter and the receiver are no longer required to have a

shared secret key prior to the wireless communication.

Background Information on DSSS

The concept of DSSS is more complicated than FHSS. DSSS is a modulation technique that can be applied to a baseband signal to increase its bandwidth. This can be achieved by multiplying an original signal by a spreading code formed by chips. This spreading code is considered as a pre-shared secret key between a sender and a receiver to expand a signal. Each spreading code is represented by a sequence of bits with values of 1 and -1 or 1 and 0 as polar or nonpolar representations, respectively (Goldsmith 2005; Simon et al. 1994). Each bit of an original message is multiplied with a spreading code, and the result is the spreading message to be transmitted through the wireless channel. A receiver does the reverse steps of a sender to despread a message. Figure 1 shows a basic DSSS communication system with two functions, including spreading and despreading.

An example of spreading and despreading a message For instance, assume that “10” is the original message and $+1 - 1 - 1 + 1$ is the spreading code used to spread the original message.

Wireless Jamming Attack, Fig. 1 Basic DSSS communication system

The sender first converts the original message “10” from a nonpolar to polar form, i.e., “10” is converted to $+1 - 1$. Then, the sender multiplies each bit of the original message with a spreading code to generate the spreading result. For this example, the result is $+1 - 1 - 1 + 1 - 1 + 1 + 1 - 1$.

To despread a received message, the receiver needs to correlate the received message with a local replica of the spreading code. In this example, the received message is $+111+11+1+11$, and the local replica of the spreading code is $+1 - 1 - 1 + 1$. The receiver aligns $+1 - 1 - 1 + 1$ with the first 4 chips of the received message (i.e., $+111 + 1$) and correlates them to get bit $+1$ (i.e., “1” in nonpolar form) and then aligns $+1 - 1 - 1 + 1$ with the next 4 chips of the received message (i.e., $-1 + 1 + 1 - 1$) and correlates them to get bit -1 (i.e., “0” in nonpolar form).

Synchronization In DSSS, identifying the beginning of a received message from the incoming bit stream is important for a receiver to recover the original message. This can be achieved by taking advantage of the autocorrelation property of the spreading code. A receiver computes the correlation between the received message and the spreading code in a sliding window way, and high correlation indicates the beginning of a message (Simon et al. 1994; Stallings 2006).

Key Applications

Jamming techniques are normally applied in tactical scenarios to block the wireless communication among the opponents. They can also be used in civilian applications to disable cell phone devices for certain purposes, e.g., preventing cheating in exams.

[Channel reciprocity](#); [Privacy amplification](#); [Quantization](#); [Reconciliation](#); [Spatial uncorrelation](#)

Definitions

Wireless key establishment is a method that allows two legitimate devices to establish a shared key utilizing the randomness inherent

in the wireless channel. In wireless context, the receiver and the transmitter of one wireless link will observe the same channel simultaneously. Such reciprocity property enables two legitimate devices to extract the same characteristics of the channel and agree on the same shared key. Meanwhile, due to the spatial uncorrelation of wireless channels, for two transmitters at different locations, the channels observed by the same receiver are different. Thus, the key established between a pair of wireless devices is confidential to a third un-located party.

Historical Background

Wireless devices have been widely used due to its remarkable evolution in the past two decades. Unlike traditional communication, a wireless device can communicate with any other device within its power range. This makes wireless communication vulnerable to potential attacks, because any devices within the power range of a wireless transmitter can receive the signal from this transmitter through the open public air. Therefore, eavesdropping becomes one of the major security problems to wireless systems. Intuitively, the communicators would like to share a common secret key, so that their conversation can be encrypted against eavesdroppers.

Traditional approaches to generate shared secret keys are mainly based on key pre-distribution schemes and public key cryptography. In the former, a centralized trusted third party generates, maintains, and distributes shared keys to communicators. However, such a scheme introduces a high key management complexity for large-scale wireless networks, which usually involve a large size of key pool and require intensive key distribution to support the key establishment between every pair of nodes.

On the other hand, public key cryptographic approaches to generate secret keys normally require the communication entities to be equipped with desired computing chips or modules, and they have been long regarded as

expensive in terms of computational complexity. For example, Diffie-Hellman algorithms, the most popular cryptographic tools to establish a shared secret key between two parties, require exponential operations on large numbers. Thus, they are not suitable for establishing the secret key among low-end wireless devices (e.g., wireless sensor nodes) that are of limited battery lifetime and computational capability.

Alternative key establishment techniques that are efficient and unique for wireless systems have been explored. There is an increasing concern about achieving fast and efficient key establishment via exploiting physical layer characteristics of wireless channels. The basic idea is to use the wireless channel reciprocity, which means that the receiver and the transmitter of one wireless link observe the same channel simultaneously. The reciprocity property of wireless channels allows two legitimate devices to establish a shared key. Due to the spatial uncorrelation of wireless channels, for two transmitters at different locations, the channels observed by the same receiver are different. Thus, the key established between a pair of wireless devices is confidential to a third un-located party. Past measurement results show that a distance of half a wavelength between the third party and the communicators can cause a mismatch about 50% between the channels observed by the third party and legitimate communication parties (Mathur et al. 2011).

Wireless channel reciprocity-based key establishment has formed a fruitful area, and it overcomes the drawbacks of traditional key establishment approaches due to its reduced computational effort and relaxed key management requirement.

Foundations

In general, a shared key is a binary bit sequence that is only known to the transmitter and the receiver. They use the shared key to encrypt and decrypt transmitted information to secure their communication. In channel reciprocity-based key establishment, a shared key is generated

from one or more channel characteristics, such as signal frequency-phase, received signal strength (RSS), and channel impulse response (CIR). It normally takes three steps to implement a channel reciprocity-based key establishment, and they are quantization, reconciliation, and privacy amplification (Wang et al. 2015). In quantization, the transmitter and receiver first sample the transmitted signal at a certain frequency, and then both of them quantize the sampled signal based on particular thresholds to generate initial binary bit sequences. Due to imperfect reciprocity and random noise, the bit sequence generated at the transmitter and the receiver from quantization may not be exactly the same. Hence, reconciliation schemes will be applied to deal with these mismatch bits. The objective of reconciliation is to correct or delete these mismatch bits using minimum channel information. After reconciliation, the transmitter and the receiver then perform privacy amplification to avoid a malicious adversary deducing the secret bit sequence. Existing approaches on wireless channel reciprocity-based key establishment mostly focus on the following critical aspects:

1. **Quantization:** Quantization is the most important part of the shared key establishment, because it provides initial information of the wireless channel. All the remaining steps expect an efficient and precise quantization output. The essential challenge of quantization is how to determine channel metrics that can fully characterize a unique wireless channel. The selection of channel metrics has a direct impact on the performance of quantization. Appropriate channel metrics (e.g., RSS, CIR, and frequency-phase information) can be used to describe a particular wireless channel and achieve a desired performance (Liu et al. 2012; Mathur et al. 2008; Ali et al. 2010; Zhu et al. 2013). Note that a good quantization performance also depends on the choice of quantization thresholds. A single threshold will lead a low generation rate, while multilevel thresholds are susceptible to the random noise.
2. **Reconciliation and privacy amplification:** Information reconciliation and privacy amplification are two indispensable steps of the wireless key establishment. Both steps collaborate with each other to achieve an adequate key generation rate with minimum information leakage. In reconciliation, devices need to exchange some channel information to correct mismatch bits. Thus, the goal of reconciliation is to minimize the channel information exchanged between the communicators, so that the chance of information leakage can be reduced. Similarly, privacy amplification aims at “amplifying” the difficulty of an eavesdropper to deduce the shared secret based on the channel information exchanged in reconciliation.
3. **Feasibility and security:** It is essential to analyze the feasibility of wireless channel reciprocity-based key establishment when they are used in a practical scenario. Investigations on the requirement they should satisfy to guarantee the generation of secret keys have been conducted since 1993 (e.g., Maurer 1993; Ahlswede and Csiszár 1993). On the other hand, using wireless channel reciprocity information to establish a shared secret key is still a developing field, and multiple attacks against such techniques have been discovered. For example, an eavesdropper may launch proximity attack (e.g., Mathur et al. 2011), in which the eavesdropper infers the secret key established between the target communicators through physically approaching to the communicators or predicting the channel characteristics between them.

Key Applications

Wireless key establishment can be applied in wireless networks especially with low-end devices (e.g., wireless sensor networks, Internet of Things) to facilitate key negotiations and preserve the confidentiality of communications between two legitimate devices.

Wireless Sensor Network and Security Issues

Wireless sensor network (WSN) is a kind of network in which several numbers of tiny nodes are deployed in such a way that they can monitor, collect data from environment, process them, and pass them using radio signal (Carlo 2014; Marco 2011; Bhaskar 2005). These are self-configured. In such situation, collaborative effort of all nodes in WSN is highly expected. Mostly sensor nodes are deployed in hard to reach area where it is very difficult to have human intervention. These are auto operated; hence, special care must be taken for energy consumption as well as external attack Scalabili WSN is high (Jaydip 2012). It provides bridge between real world and virtual world (Marco 2011). Key Application of WSN by looking the versatility and flexibility of WSN, these are implemented in various fields of applications including agriculture, medical, engineering, environmental science, water resource management, industrial engineering, security and surveillance system, transportation, smart grid application, etc. (Bhaskar 2005); in spite of having so many scopes for implementation, these are suffering from some limitations including proper security features.

Figure 1 shows the different layers of WSN. In most of WSN, basically five different layers are available, namely, application layer, transport layer, network layer, data link layer, and physical

Wireless Sensor Network Security, Fig. 1 Layer structure of WSN (Kavitha and Sridharan 2010)

layer. Functions of these layers are more or less same as that of any other network layers. Apart from these, another three cross layers are also available to take care of special function of WSN. These are, namely, power management layer, mobility management layer, and task management layers.

WSN security primarily includes prediction, detection, and prevention of unauthorized access of network, stealing, modification, or disruption of resources, disturbing users from unnecessary mail, pop-up, monitoring user activities without authorization, and more consumption of network resources such as bandwidth, power backup, etc.

It also includes protection of different threats and attacks. Even while protecting the threat and attack, it must be concerned that it should not disrupt the normal activities of the network. Otherwise due to lack of inefficient security services, the user may face lots of problem.

People are working on different ways to prevent WSN from all sorts of security faults. Some of the ways are given below.

Passive network security devices understand the malicious network traffic, and accordingly it prevents the traffic and save the network from attacks.

But the active security devices resist the specific network traffic to keep the network function intake.

With the help of preventive security devices, network administrator can understand the potential threat and alert the user to take preventive measures.

Applications or devices are built in such a way that they understand potential attack, unauthorized network traffic, or any other threat that network may face.

Specifically for sensor network, there must be auto protected system as it is quite difficult to maintain the same manually on regular basis. While transmitting data from various sensor nodes to base station, it should be in encrypted format so that external attacker is not able to get data easily. Any partially or fully disabled sensor nodes should be remotely blocked.

Attacks in WSN

Types of attack that are found in the case of WSN are shown below (Vikash et al. 2014).

Due to unique characteristics of WSN and lack of constraints in hardware and software, WSN is very much vulnerable to different kinds of attack (Pathan et al. 2006). Sensor nodes communicate among themselves over wireless link; it leads them to eavesdrop on. An attacker may easily push the malicious data into the network. Denial-of-service attack may take place easily in WSN (Pathan et al. 2006; Anwar et al. 2014; Kavitha and Sridharan 2010; Vikash et al. 2014).

Attacks are also defined as outsider as well as insider attack. In case of outsider attack, attackers are not a part of WSN. It may cause passive eavesdropping on data transmission, or it may inject malicious data into the network with a motive to consume network resources.

But in case of insider attack, legitimate nodes of WSN may compromise with attackers, or independently it may attack the system. These are more dangerous because the trusted nodes of the network may break the authentication system and exposed the confidentiality of the network. It is very difficult to understand the attack pat-

tern. Even the attackers suppress the regular data flow from various nodes to BS. Due to packet-dropping attack of this kind, network performance is gradually coming down (Kavitha and Sridharan 2010; Kahina 2015).

WSN is suffering from both active and passive attack. Active attacks are kinds of attack in which attackers are silently monitoring the system, data forwarding, channel blocking by flooding packets in the network, diverting data, dropping packets, routing disorder, malfunctioning the nodes, etc. Here attackers take the control over the network. Passive attacks are kinds of attack in which attackers are listening or monitoring the traffic, analyzing traffic, stealing authentication-related data, breaking data encryption system, disclosing data, etc. (Vikash et al. 2014; Kahina 2015).

Basic classifications of attack are (Vikash et al. 2014):

1. Active Attack
 - 1.1 Routing Attacks in Sensor Networks
 - 1.1.1 Attacks on Information in Transit
 - 1.1.2 Selective Forwarding
 - 1.1.3 Black Hole/Sinkhole Attack
 - 1.1.4 Wormhole Attacks
 - 1.1.5 Hello Flood Attack
 - 1.2 Denial of Services
 - 1.3 Node Subversion
 - 1.4 Node Malfunction
 - 1.5 Node Outage
 - 1.6 Physical Attacks
 - 1.7 Message Corruption
 - 1.8 False Node
 - 1.9 Node Replication Attacks
 - 1.10 Passive Information Gathering
2. Passive Attack
 - 2.1 Monitor and Eavesdropping
 - 2.2 Traffic Analysis
 - 2.3 Camouflage Adversaries

Routing attack is a network layer attack. Different kinds of attack under this category include. In case of attacks on information in transit, the attacker monitors the traffic, and as per requirement, they can spoof, alter, and replay the traffic to modify, interrupt, or intercept the packet.

Though it is expected that sensor nodes should forward the traffic, yet in some cases, nodes may compromise with attacker and selectively forward the packets instead of forwarding all data.

In case of blackhole attack, attacker drags all the traffic toward it. As a result of this destination is failure to get data.

In wormhole attack, attacker replays the broadcast request packets that it receives from source to its neighbors and convinces them in such a way that as if the source is one hop away from it, thus tunneling the packets in different directions.

In Hello flood attack, the attacker sends high-powered Hello messages to its neighbors. By this, adversaries advertise themselves to the neighbors so that neighbors understand that path through the attacker is superior than any other available paths. This attack is a very dangerous attack because it consumes high amount of network resources which ultimately leads to low network performance.

Denial-of-service (DoS) attack may be data link layer attack or network layer attack. Here, attacker may inject fake bogus packets in the channel to force security measures. As a result of this, network fails to maintain the network primitives like availability, integrity, and confidentiality.

Sometimes, some sensor nodes of the network may compromise with the adversaries and disclosing the security key to the attacker. Hence confidentiality of the network is not maintained. Such kind of attack is categorized under node subversion.

Node malfunctioning may corrupt the entire system by generating unnecessary data to lose the data integrity of the system.

In some situation, sensor node may suddenly fail to work due to physical, location, or software problem. But in case of outage attack, the attacker intentionally creates the situation to break down the ongoing data path.

In physical attack, attacker may destroy any hardware of the sensor node by tempering the circuitry.

In message corruption attack, original message is tempered with malicious data.

In false node creation attack, attacker creates false node in the network, misleading the genuine nodes. Thus data delivery process as well as network resource is getting down.

In node replication attack, attacker replicates the existing node by identifying sensor node's ID. This attack may quickly degrade the network resources like bandwidth, battery power of the nodes, etc. which are considered as major concern for sensor network.

Some malicious nodes may silently monitor the network traffic and collect required data from the network. This is categorized under passive information gathering attack.

In case of passive attack, also adversaries monitor the traffic and snooping data during communication. In traffic analysis attack, attacker analyzes and tempers data accordingly. Camouflage adversaries may focus themselves as an actual node in the network and divert the packets to different directions.

Basic Security Scheme for WSN

Unlike any other network, any kind of security schemes cannot be implemented in WSN. The tiny nodes in WSN are designed in such a way that they consume less energy. Irrespective of their configuration, if any kind of security features are implemented then it may lose the basic network primitives such as authentication, integrity, privacy, nonrepudiation, and anti-playback. Some of the security features that are implemented in WSN are as follows:

(a) Cryptograph

Data encryption and decryption technology for a wired or other wireless network are not the same as that of implementation in WSN (Pathan et al. 2006). WSN contains tiny nodes which are very much concern about resources. At the same time, cryptographic algorithm is resource consuming. Since WSN suffers from several limitations including battery power, small memory, etc., traditional cryptographic algorithm is quite difficult to implement (Pathan et al. 2006; Rawya

and Yasmin 2015; Madhumita 2014). Of course, various cryptographic algorithms are proposed to meet the security requirements including authenticity, confidentiality, and data integrity (Rawya and Yasmin 2015). There are two different ways to protect the system, namely, symmetric and asymmetric algorithms. Some examples are AES (Advanced Encryption Standard), ECC (Elliptic Curve Cryptography), RC4 (Rivest Cipher 4), RC5 (Rivest Cipher 5), RSA (Ron Shamir and Adleman), etc. (Daniel et al. 2017). Symmetric algorithm is cost-effective and secure enough. Of course, sharing of secret key may be an issue. Though asymmetric algorithm is able to resolve the problem of sharing of secret key, these are more resource consuming and slow. In some cases, hybrid algorithm is proposed (Rawya and Yasmin 2015). In Rawya and Yasmin (2015), authors designed an algorithm in which two phases are included; in phase I, both symmetric and asymmetric algorithms like AES and ECC are used. In phase II, XOR-DUAL RSA is used for security in addition to hashing and MD5 for data integrity.

(b) Steganography

In contrast to cryptography, steganography hides the message existence (Pathan et al. 2006; David and Hervé 2012). This is one of the best methods to secure data as external users are generally unaware about the existence of the message (Reetika and Anshul 2017). In this method, carrier is modified so that it is not perceptible. In Reetika and Anshul (2017), authors propose a system in which steganography technique is used for data hiding in WSN, and then various parameters like MSE, PSNR, AMD, energy consumption, network lifetime, etc. are calculated.

(c) Physical Layer Secure Access

It is a method which uses frequency hopping. The method uses available frequency set, dwell time, and hopping pattern. Efficient design is one of the most important parts

of this method. Also the synchronization of sender and receiver is another important issue (Pathan et al. 2006). It is for intrinsic security process induced based on physical layer capabilities like SNR (signal-to-noise ratio) gap, intended jamming, randomness of channel, etc. (Jinho et al. 2013). This security feature tries to hide the existence of certain nodes though ongoing communication is available. This process works fine unless and until the existence of hidden nodes is not disclosed to adversaries. Some of the existing physical layer security approaches included secrecy capacity, channel signature, spectrum spreading of signal energy, cooperation, etc. (Tommaso et al. 2016).

(d) Watermark

Watermarking technique has been widely used in intellectual property protection like text, audio/video, circuit design, and data security in sensor network (Jennifer et al. 2016). Due to lack of some limitations of cryptographic security solutions, it is identified that watermarking security solutions are proposed due to its light resource requirements (Bambang et al. 2012).

Security Challenges

Security challenges are very important in WSN. Some of the security challenges available for WSN are given below (Daniel et al. 2017; Madhumita 2014; Raja et al. 2014).

Authenticity: Any intruder may be part of the network. Like any other nodes available in WSN, it may also try to penetrate malicious data into the network. Hence, anything coming from authorized nodes must be verified so that the network can maintain its security.

Availability: While implementing security features, the user must concern about the availability of sensor nodes. There may be two different points of concern: firstly, the network must understand about the availability of all nodes. If not, it must find the valid cause. Secondly, after

implementation of security features, nodes must work like normal nodes.

Confidentiality: It is another important point to be concerned so that the data should not be disclosed to any intruder.

Freshness: Security measures also consider the point of data freshness. On time data delivery and availability of data is one of the major points of concern.

Integrity: Data integrity is a point where data consistency as well as data privacy is maintained so that attacker cannot modify, delete, or drop the data.

Localization: Localization implies the sending and receiving of expected data to and from the actual nodes.

Conclusion

From various studies, it has been seen that WSN has vast applications in current scenarios. It has some unique features which makes them different from other networks. Smart nodes in WSN are mostly collecting data from the environment, then process them, and send these data to BS. Due to its flexibilities in applications as well as easy implementation, these are suffering from various kinds of limitations including different attacks. Lots of research works are going on to detect and eliminate those attacks from WSN.

Definition

An effective urban traffic management system intends to manage traffic effectively by leveraging wireless sensor networks enabled processing technologies and intelligent system algorithms for smart cities.

Historical Background

Generally speaking, Wireless Sensor Networks (WSNs) consisting of a group of resource-constrained sensors to collect data from surrounding environments are becoming key components in the emerging areas of cyber physical systems. On one hand, energy efficiency is crucial for most sensors due to battery supply. On the other hand, topology management and network coverage are also significant in

WSNs (Haque and Abu-Ghazaleh 2016). In general, the main research background of WSN-enabled traffic management is involving from capacity increase, mobility support to quality of experience improvement.

The study of Internet of Vehicles (IoVs) has sprung up, where vehicles are viewed as sensor hubs to capture information by in-vehicle sensors for kinds of mobile applications. Based on the research report from BI Intelligence in 2015, 75% of cars will be equipped with network devices to enable Internet access on roads by 2020. The deep integration of intelligent sensors and communication technologies opens up a new frontier for IoVs in smart cities. Thanks to the development of communication and information technologies, connected vehicles in IoVs are playing a crucial role for urban traffic management, such as road safety improvement and transportation efficiency enhancement.

The rapid development of WSNs in vehicular networks enables high-efficient traffic management. A comprehensive survey of traffic management system in smart cities is conducted in Djahel et al. (2015), from the aspects of information collection to that of service delivery. The data sensing and gathering phase can measure traffic parameters, e.g., traffic volume and speed, through road-monitoring equipment. After that, the generated information is periodically reported to a management entity. Because the data are fused and aggregated during the data fusion, processing, and aggregation processes, how to extract useful information for traffic management is significant. The data exploitation phase employs the obtained knowledge through the data processing phase to select optimal routes for vehicles, forecast short-term traffic, and provide road-traffic statistics. In the service delivery process, the traffic management system forwards the acquired knowledge to terminal users through devices, e.g., smartphones and vehicle onboard units.

Due to the high mobility of vehicles equipped with sensors, traffic management in urban areas still faces several challenges. Sink mobility management is generally regarded as an effective method to promote performances in WSNs, such

as it can relieve the traffic burden for a group of network nodes. The corresponding sink mobility management schemes can be classified into four categories: uncontrollable mobility, path-restricted mobility, location-restricted mobility, and unrestricted mobility (Gu et al. 2016). The behavior of mobile sinks has direct impact on the performance of uncontrollable mobility. Its main challenge is lacking of sink information to update sink location and forward information. Path-restricted mobility is related to the geographic constraints, i.e., vehicles attached by sinks collect data by moving along certain roads. Under this circumstance, how to collect data, such as speed and routing information is challenging. Location-restricted mobility has a direct relationship with the sink location, i.e., sinks merely stop at some locations for data collection. Different from path-restricted mobility where the sink trajectory is predetermined, and location-restricted mobility where the stops are fixed, unrestricted mobility generally embraces the issues of not only data routing but also motion control.

For the sake of realizing high-efficient urban traffic management, three critical issues deserve to be investigated: (1) Real-time traffic condition perception: The various high-resolution roadside and on-board sensors require to be deployed to sense real-time traffic circumstances, such as location, speed, road throughput, and weather condition; (2) Low-latency communication and massive-data storage: Sensors equipped by vehicles generate vast amount of data with distinct data types, sizes, and dimensionality, challenging the communication bandwidth, data processing speed, and storage capability of current vehicular networks; (3) Traffic prediction and real-time responsiveness: The generated traffic data from various sources can be leveraged to monitor traffic density and road throughput in a real-time manner, so that prompt decisions can be made according to the network prediction to guide traffic flows. Some open issues are how to design a context-aware system for traffic light control to reduce the waiting time at road intersections, how to construct a real-time response system for accident rescue, and how to design an accurate model to estimate network

traffic according to the obtained massive traffic data (Nellore and Hancke 2016).

Key Applications

WSN-enabled urban traffic management is promising for smart cities, and some applications have been well discussed by the previous researches. In this section, we focus on some emerging applications for urban traffic management.

Deep Learning-Based Traffic Management

In recent years, deep learning has become a breakthrough methodology in machine learning for distinct research fields in computer science and other disciplines. However, it should be noticed that the recent endeavors to train deep learning architectures for network traffic control generally concentrate on some benchmark routing protocols, which cannot cope with the increasingly complex network circumstances due to the lack of computing intelligence (Fadlullah et al. 2017). To overcome these limitations, the integration of deep learning and network traffic optimization is promising to make intelligent routing decision for message forwarding. Furthermore, effective traffic control in wireless backbone networks is also significant. The reasons are the traditional routing schemes with network abnormality cannot learn their knowledge from previous experiences. Intelligent network traffic control enabled by real-time deep learning is advocated, which can integrate deep convolutional neural networks with unique input and output characters to describe the character of network backbone.

Another key application for deep learning-based traffic management is automated vehicles (acknowledged as driverless cars or self-driving vehicles as well), thanks to the rapid development of advanced sensors in situational awareness and autonomous navigation systems. However, various sensors equipped on vehicles need to be integrated, challenging the design of machine learning-based traffic management for real-time driving decisions. Recently, deep neural networks

have also been leveraged to analyze the generated multi-modal information by sensors for automated vehicles.

Smart Parking

Due to the ever-increasing volume of traffic congestion, smart parking has become a needpress from the viewpoint of both research fields and economic interests. By leveraging the advanced sensors to collect information for communication, drivers can find suitable parking spaces effectively. Generally speaking, smart parking solutions include information collection, system deployment, and service dissemination. A comprehensive overview of the available sensing technologies can be provided by the information collection to check the current empty parking space of parking lots. Among the WSN-enabled smart parking solutions, how to guarantee the identification and transmission of vehicular information are two main research topics. The identification of vehicular information depends on sensors for environment detection. The transmission of vehicular information relies on the integration of sensors and citywide infrastructures to collect information. Currently, crowdsensing and shared parking are two promising WSN-enabled urban services for smart parking. Software system exploitation and data analysis are the main concentration of system deployment. The corresponding software embraces guidance, reservation, E-parking, and information monitor for both managers and users. Driven by WSNs, the collected data can be leveraged to provide an analysis for urban traffic management. The relationship between information and social features reflects service dissemination. Due to individual behavior, information dissemination and parking competition are becoming two main issues. The former has a direct relationship with communication patterns among vehicles, while the latter happens due to the limitation of network resource.

Smart LED Streetlight

Owing to the development of low-power and low-cost WSNs, such as ZigBee, LoRa, and

Sigfox, our city is becoming smarter than ever before, where smart traffic, smart energy, and smart streetlight system become realized. A rather practical question is how to fuse the sensed data in a comprehensive manner for effective urban traffic management. It is well acknowledged that WSNs are very suitable for LED streetlight systems, which can be viewed as a core application for vehicles and pedestrians by providing low-cost and low power outdoor lighting. The combination of sensors and ZigBee-based wireless sensor modules is able to offer a platform for LED streetlight applications. In Daely et al. (2017), the authors designed a smart LED streetlight system by integrating public weather data, ZigBee-based wireless communication, and web-based management system for urban traffic management.

Energy Harvesting in Vehicular Networks

Energy harvesting is promising for energy-constrained wireless networks, such as WSNs and vehicular networks (Atallah et al. 2016). The former consists of sensors with limited lifetime, and the latter contains low-cost and battery-powered roadside units in rural areas or along highways. Through the conversion from energy to direct current voltage, energy harvesting becomes a research hotspot to prolong the battery lifetime of electronic devices. The corresponding applications enabled by WSNs cover traffic monitor, health monitor, and so on. Energy harvesting solutions can also be leveraged to operate and charge a large number of low-power devices. Radio frequency-based energy transfer and harvesting techniques are effective solutions to extend the lifetime of battery-based sensor nodes.

Smartphone-Based Vehicle Telematics

Smartphone is becoming a modern kind of sensors, which can offer various kinds of services and applications for our daily life. The integration of smartphones and vehicular networks is advocated for urban traffic management, which is not only cost effective but also can facilitate various components in urban traffic management

systems (Wahlström et al. 2017). However, the IEEE 802.11p interfaces are not equipped by commercial smartphones.

Although it is demonstrated that smartphones are not necessary to be compliant with the IEEE 802.11p standard, it is challenging to fulfill the sensing, computing, and storage capabilities of smartphones before forwarding the sensed data to an in-vehicle 802.11p device through Bluetooth or WiFi. The consumed energy by hardware during application running is a core factor for smartphones. Besides, black boxes installed by vehicles or vehicle's on-board system can acquire information, monitor, and feed back the performance of vehicles for traffic management. As the emerging of crowdsourcing/crowdsensing and sharing economy, how to fuse information from vehicles, pedestrians, and local infrastructure challenges the design of cooperative intelligent transportation systems, especially for individuals with limited sensing ability or within a limited geographical region.

Definitions

Wireless video delivery refers to a video transmission technology over wireless channels and networks. A sender, e.g., content server, base station, and Wi-Fi access point, encodes video frames and transmits the encoded video frames over wireless links/networks. The transmitted video frames are impaired by losses and effective noise due to limited bandwidth and unstable channel quality. The receiver, e.g., laptop, smartphone, and tablet, receives the transmitted video frames and decodes the video frames for playback.

Historical Background

Video streaming over the Internet was born in 1993, and a commercial product of Internet video streaming was started in 1995. For realizing wireless multimedia delivery including video delivery, the first concept of the mobile multimedia device was shown by Sheng et al. (1992). One of the major issues in wireless video delivery is that video streaming requires high throughput to deliver high-quality video, while the capacity of wireless links/networks is considerably limited compared with wired links/networks. To discuss the feasibility of video streaming in band-limited wireless links/networks, video streaming over (very) low bandwidth links has been studied since 1994. For example, Khansari et al. (1994a) and Pelz (1994) consider the transmission of video frames in the Quarter Common Intermediate Format (QCIF) over the wireless links with an available data rate of 64 Kbits/s. They demonstrated the feasibility of wireless applications by using a video encoder/decoder with sophisticated signal processing and error correction techniques. From 1995, many video delivery techniques under the consideration of wireless link features, which are referred to as “cross-layer” techniques, have been studied for high-quality, reliable, and scalable wireless video delivery. Specifically, the existing cross-layer studies mainly tackle (1) efficient video delivery under limited throughput, (2) robustness to various channel conditions, and (3) scalability for multiple wireless devices.

Efficient Video Delivery Under Limited Throughput

As mentioned above, video delivery applications traditionally require a higher-throughput requirement due to a large amount of traffic. If the amount of video traffic is higher than the available throughput, it causes stalls during video playback and low user's satisfaction for wireless applications. To efficiently deliver video contents within an available throughput without stalls, existing studies on wireless video delivery mainly use two types of coding techniques to reduce the expected distortion of the received video contents

since 1994: scalable (layered) video coding and rate control.

For example, Khansari et al. (1994b) designed layered coding techniques for wireless video delivery. Specifically, they consider two paths (high and low rates) in end-to-end video session and send low- and high-frequency-domain coefficients in high-rate and low-rate path, respectively. Here, low-frequency coefficients provide baseline quality of video contents, while high-frequency coefficients enhance the quality of the video contents. Song and Chen (2007) proposed a joint application and physical layer design to transmit scalable video over multiple-input and multiple-output (MIMO) wireless systems. In this system, scalable video coding (SVC), such as H.264/SVC (Schwarz et al. 2007), generates layered bitstreams in application layer. At the physical layer, each subchannel's quality can be obtained by partial channel information. Finally, higher priority layer bitstream will be transmitted over higher-quality subchannel to realize unequal error protection for high-quality video delivery.

In the rate control, Ortega and Khansari (1995) proposed a rate control algorithm of the video encoder for variable bit rate in wireless links/networks. To realize better video quality under a variable bit rate, they use a channel model based on a Markov chain model for rate control to predict future channel behavior. From evaluations, they demonstrated the rate control algorithm with the estimated channel model keeps better video quality without actual channel information. Hsu et al. (1999) also proposed a rate control algorithm under the consideration of a time-varying burst loss. They consider the two-state Markov model and N-state Markov model for estimating burst loss into the rate control. Stankovic et al. (2004) designed two types of the bit allocation algorithms for forward error correction (FEC) systems in packet erasure and flat-fading channels. Specifically, the first algorithm provides Reed-Solomon (RS)-based unequal loss protection across source packets in packet erasure channels to maximize the average number of correctly decoded source bits. The second algorithm provides a product

code protection, i.e., the combination of RS code and an outer cyclic redundancy check (CRC) code/inner rate-compatible punctured convolutional (RCPC) code, for transmission over wireless channels including flat-fading.

Robustness to Various Channel Conditions

It is known that digitally encoded video data is susceptible to errors during wireless transmissions. In the standard video encoders, pixel values are transformed into frequency-domain coefficients by using discrete cosine transform (DCT) or wavelet and then quantized the coefficients. The quantized coefficients are finally compressed by variable length coding (VLC), i.e., Huffman coding. In VLC, even a single bit error can cause the loss of entire video data. In wireless data transmissions, error correction schemes are usually used for reliable communications. However, they generally have an all-or-nothing behavior for error correction. It means each received packet is either entirely correct or discarded according to the number of bit errors in each received packet. If a received packet contains bit errors, it causes significant degradation in received video quality.

Hanzo (1998) investigated the impacts of modulation and channel coding schemes on the received video quality in additive white Gaussian noise (AWGN) and Rayleigh fading channels. From the evaluation results, wireless video delivery suffers significant quality degradation at a low channel quality due to many bit errors. This phenomenon is called cliff effect. In addition, the video quality does not improve even when the wireless channel quality is improved. This is called leveling effect. This is because quantization is a lossy process, and its distortion cannot be recovered at the receiver. Cherriman et al. (1999) also investigated the impacts of frequency-selective fading on the received video quality. Here, they use Orthogonal Frequency-Division Multiplexing (OFDM) for dispersive channels to convey high-rate video contents.

Ji et al. (2003) solved the problems of video broadcasting over the OFDM-MIMO systems. In OFDM-MIMO systems, it takes advantage of both layered video coding and OFDM-

MIMO subchannels by matching the source layers of higher importance into the spatial subchannels with higher channel gain. The layered video source should be encoded into multiple descriptions (replicas) for OFDM-MIMO broadcast to guarantee consistent performance over various subchannel gains. Here, FEC code-based multiple description coding (MDFEC) is applied to the layered video source for multiple description coding. Ahmad et al. (2016) designed a cross-layer framework for multiuser wireless video streaming under the consideration of time-varying interference. A main challenge is to realize joint power control and rate adaptation to provide fair streaming quality across the users in time-varying wireless channels. They modeled the problem as a stochastic control problem and proposed a risk-sensitive control approach considering a nonlinear cost function to provide the optimal solution.

Scalability for Multiple Wireless Devices

When multiple users request the same video content/different video contents within the wireless links at the same time, it needs to share the same spectrum across the multiple wireless devices. In this case, a collision will occur when two or more wireless devices try to access the same spectrum at the same time. To efficiently share the spectrum, medium access control (MAC) protocols have been proposed for wireless communications. MAC protocol regulates channel access across multiple wireless devices to share the spectrum effectively and fairly. MAC protocols are usually classified into two types: contention-based and contention-free controls. The contention-based MAC protocol is a distributed approach that shares the spectrum among competitive devices. The contention-free MAC protocol brings the network up from a competitive state (where collisions may occur) to a collision-free state. The contention-free MAC protocols are often used in wireless video delivery because they can guarantee collision-free delivery.

On the other hand, with the growing demand for video applications, the MAC protocols need

to support various video applications with various Quality of Service (QoS) requirements. Specifically, real-time video applications require delay-sensitive controls, while video on demand (VoD) and multimedia surveillance applications need to support continuous connections between the sender and the receiver.

Other solutions to efficiently share the spectrum across multiple wireless devices are resource allocation of wireless medium and scheduling across the devices. Huand et al. (2008) considered efficient multiuser video streaming over wireless networks. A main objective is to maximize the received video quality of a limited number of video users, without interrupting the service of the coexisting voice users. For this purpose, they proposed a joint framework of network resource allocation, source adaptation, and deadline-aware scheduling for wireless multiuser video streaming. Specifically, they developed a joint algorithm, which consists of wireless resource allocation based on the video user's utility function, source rate adaptation based on content summarization, and packet scheduling to satisfy each video user's deadline constraints. Ji et al. (2009) solved the problems of scheduling and resource allocation for multiuser scalable video streaming over downlink OFDM systems. They proposed a scheduling and resource allocation algorithm across multiple users based on the users' priority weights calculated by the video contents, deadline requirements, and transmission history to thoroughly explore the time, frequency, and multiuser diversities of the OFDM system. He and Liu (2014) designed a cross-layer scheme with the packet scheduling and resource allocation algorithms to maximize the received video quality with the limited network resource and the deadline constraints over Orthogonal Frequency-Division Multiplexing Access (OFDMA) network. The proposed scheme considers the information extracted from the application layer, MAC layer, and physical layer and formulates the packet scheduling, subcarrier assignment, and power allocation into a mathematical model.

Recent Viewpoints in Wireless Video Delivery

Even since the 2010s, novel cross-layer techniques on wireless video delivery, including soft video delivery and video-application-aware MAC protocols, have been proposed under the considerations of video contents and wireless channel features to provide better video quality at wireless devices.

Soft Video Delivery

In conventional video delivery, they use VLC to compress the quantized frequency-domain coefficients and send the compressed bits to wireless devices. If bit flips occur by bit errors during wireless video delivery, it causes synchronized problems in video decoding and significant quality degradation. In addition, different wireless devices experience quite different wireless channel qualities, and each channel quality is usually unpredictable in practice. It means optimized quality adaptation according to each device's channel quality is not easy and sometimes suffer from cliff effect.

To realize better quality adaptation without actual channel information, Jakubczak and Katabi (2011) proposed soft video coding and decoding for wireless video delivery. In soft video delivery schemes, they use linear analog coding instead of VLC for compression. The analog coding mainly consists of three-dimensional DCT (3D-DCT), power allocation, and Walsh-Hadamard transform. 3D-DCT compacts video information by using spatial- and time-domain correlations between video frames. The power allocation scales each DCT coefficient according to the significance of the DCT coefficient to protect from effective noise. Walsh-Hadamard transform randomizes all the scaled coefficients. As a result, all packets have equal energy, i.e., significance, and thus realize better loss resilience.

By using analog coding for wireless video delivery, it can prevent significant quality degradation due to bit errors and packet losses, instead, realize graceful quality improvement with the improvement of wireless channel quality. Soft

video delivery schemes remove variable length digital coding for compression to prevent significant quality degradation due to synchronization problems.

Video-Application-Aware MAC Protocols

Video-aware MAC protocols have been proposed to satisfy various QoS requirements in wireless video applications. Specifically, the existing MAC protocols designed for delay-sensitive and quality-sensitive applications.

Wang and Zhuang (2009) and Chen et al. (2010) proposed contention-free and contention-based MAC protocols, respectively, under a certain delay constraint. In Wang and Zhuang (2009), they designed time-division multiple access (TDMA)-based MAC protocol for wireless video applications. Specifically, the time is partitioned into multiple slots of constant duration. Here, each slot consists of two-portions: control part and transmission part. The control part also consists of one or more real-time minislots and multiple non-real-time minislots. Each sender is allocated to each non-real-time minislot and thus sends a jamming signal at the corresponding minislot if the sender wants to send a packet. If the packet has a certain delay constraint, the sender also sends a jamming signal at the real-time minislot to guarantee QoS requirements of video applications.

In Chen et al. (2010), they proposed a content-aware retry limit adaptation scheme at the MAC layer for wireless video delivery. In IEEE 802.11-like networks, they use a retry mechanism, in which a lost packet is retransmitted several times up to a predefined retry limit. This may cause quality degradation because a packet may arrive later than the presentation time. The proposed scheme adaptively decides the retry limit of each packet based on the loss impact. Specifically, they calculate the amount of decoding errors for each packet when the packet is lost. If the amount of decoding errors is large, they assign high retry limit to decrease the impact of packet loss on the received video quality.

Baik et al. (2015) proposed contention-based MAC protocol considering the perceptual video quality into frame retransmission strategy. They

first figured out an impact of frame loss at MAC layer on visual quality. Based on the investigation, they adaptively decide the retransmission at MAC layer. For example, even when a transmitted frame is lost, a sender does not retransmit the frame when the user will accept the received video quality. By reducing the number of retransmissions under the consideration of perceptual video quality, it maintains the quality of wireless video applications with the reduction of network delays.

Key Applications

High-quality, reliable, and scalable wireless video delivery is required for low-resolution video contents as well as high-resolution and immersive video contents, e.g., multi-view video, free viewpoint video, and 360-degree video (Fujihashi et al. 2019). For example, multi-view video is an emerging and attractive technique to observe a three-dimensional (3D) scene from freely switchable angles. Multi-view video consists of multiple cameras' video captured by closely spaced camera arrays. A sender conveys video frames of multiple cameras over wireless links/networks, and each wireless user freely switches the viewing camera during video playback to figure out the preferred viewpoint of the scene.

Although main applications of wireless video delivery are downlink, uplink-based high-quality wireless video delivery is also required for recent wireless video applications such as crowdsourced video applications and video surveillance (Nu et al. 2018). In crowdsourced video applications, users can share and report the experience with other users by uploading video contents captured at a crowded event.

Definitions

Wireless video streaming is a kind of real time video delivery pattern over wireless networks.

Historical Background

Video streaming is one of the most popular applications for wireless and mobile networks. Starting from the mid-1990s, many works focused on performance analysis for real time video delivery over wireless networks. A large amount of attentions was given to enhance video coding in order to combat errors introduced by the wireless chan-

nel variability. Stuhlmüller et al. (2000) derived a theoretical framework for the picture quality after video transmission over lossy channels, based on a 2-state Markov model describing burst errors on the symbol level. Zhang et al. (2000), Li et al. (2016), Liu et al. (2018), and He et al. (2002) proposed methods for estimating the channel distortion and its impact on performance.

Video streaming over wireless networks is increasingly the technology of choice for a wide range of important applications, including remote surveillance, security monitoring, smart home, environmental tracking, and battlefield intelligence. A major challenge in wireless streaming is that the channel is time-varying and error-prone. In video streaming over wireless channels, each video packet can be received correctly, received with errors, or lost over the network. If a video packet is received with errors, the error bits will cause decoding failure of the packet. In this case, the video decoder often discards the packet and jumps to the next one to continue the decoding process. Major causes of packet loss include network congestion and buffer overflow. In real-time applications, video transmission has a delay constraint, i.e., the video packet has to arrive at the decoder before the scheduled playback time. In video transmission over shared wireless channels, packet delivery often experiences significant delays. These works mainly focused on ensuring robustness of video delivery over a variable wireless channel.

Streaming media over wireless networks is becoming an increasingly important application. An Unequal Error Protection (UEP)-based error control scheme for transmission of low bit rate MPEG-4 video over wireless channels is proposed, where MPEG-4 bitstream is divided into two classes, and UEP is applied to each class of data.

Later on, there has been a tremendous growth in streaming media applications, thanks to the fast development of network services and the remarkable growth of smart mobile devices. HTTP Live Streaming (HLS) (Apple Inc), Silverlight Smooth Streaming (MSS) (Zambelli), HTTP Dynamic Streaming (HDS) (Adobe Systems Inc), and Dynamic Adaptive

Streaming over HTTP (DASH) (DASH Industry Forum) achieve decoder-driven rate adaptation by providing video streams in a variety of bitrates and breaking them into small HTTP file segments. The media information of each segment is stored in a manifest file, which is created at server and transmitted to client to provide the specification and location of each segment. Throughout the streaming process, the video player at the client adaptively switches among the available streams by selecting segments based on playback rate, buffer condition, and instantaneous TCP throughput (Stockhammer 2011). Specially, Zhang et al. (2016) and Liu et al. (2014) study the influence of network coding of free viewpoint video for wireless streaming.

The video sources for most streaming applications are typically precoded video sequences with relative high bit rates. However, the currently deployed wireless cellular systems are designed to only support lower bit rate data. In order to support video streaming over such networks, the high rate video sources need to be processed through a variety of schemes, such as scalable video stream extraction, transcoding, and summarization before they can be accommodated by the wireless channel. Different video content segments have different rate-distortion characteristics, e.g., some segment may be part of an action movie and requires a lot of bits to encode, while others may be just static video frames that require relatively less bits. In a wireless multiaccess channel, the type of multiuser content diversity in content rate-distortion characteristics should be taken into consideration while optimizing the network resource.

In summary, wireless video streaming has great application value in the field of streaming media.

Foundations

For Wireless video streaming, in general, media players at the devices are equipped with a playout buffer that stores arriving packets. As long as there are packets in the buffer, the video can

be played smoothly. However, starvations of the buffer can cause large jitters and are particularly annoying for end users that see frozen images. One feasible way to avoid starvations is to introduce a start-up (also called prefetching) delay before playing the stream and a rebuffering delay after each starvation event. Then after a number of media frames accumulate in the buffer, the media player starts to work.

Indeed, wireless channel is subject to a large variability due to fading, mobility, etc. For example, in 3GPP LTE cellular network, receiver bandwidth is defined as a certain number of Physical Resource Blocks (PRB) in both time and frequency domain. The more PRBs are assigned to one user, the more bitrate he can enjoy. In Sallabi and Shuaib (2011), a Finite State Markov Channel (FSMC) model is proposed to estimate the bandwidth of LTE wireless network. The states are determined by partitioning the average received Signal to Noise Ratio (SNR) range to K intervals, where $K-1$ is the number of Modulation Coding Scheme (MCS). The variation of PRBs can be modeled as a stationary Markov chain, with state space $S = \{S_0, S_1, \dots, S_M\}$. The state space contains K different PRB states with corresponding bit per symbol rate; each state records the number of RRB available. Let π_i is the probability of stationary state i and π_i is the onestep transition probability from state i to state j , where $i, j \in \{0, 1, \dots, K-1\}$. The model is illustrated in Fig. 1. Here we give an example to further explain this; the MCSs recommended by 3GPP are QPSK, 16QAM, and 64QAM. These three MCSs lead to four intervals and four states. We can estimate the real-time bandwidth of wire-

less channel based on this model. Then whether the video streaming will stall or not can be known by comparing the available bandwidth with the video bitrate.

Streaming video services can be classified into three major types: Real-Time Streaming Service (RTSV), Near-Real Time Streaming Service (NRTSV), and Download service (R1-083233 2008). The RTSV service type is suitable for interactive video conferencing applications. The primary constraint for this type of service is guarantees on the end-to-end latency of the video frame transmission.

The NRTSV service is suitable for noninteractive streaming applications, which can be either live streaming or streaming of archived media. At the beginning, the video frames of the stream are buffered into a preroll buffer, or de-jitter buffer. The playout begins after the buffering delay, which is typically several seconds, e.g., 5 s to 30 s. The primary guarantee required for this service is that there is always a video frame available for playout in the preroll buffer after the playout begins.

The Download service is suitable when the mobile terminal has a large storage available to download and save the video stream, which can be played out later. There are two types of Download services possible: complete download service (also known as cache and carry) and progressive download service. In complete download, the entire video stream is downloaded and stored into the mobile device; it can be played at a later time at the user's discretion. In the progressive download service, the mobile device starts playout after downloading a fraction of the

Wireless Video Streaming, Fig. 1 FSMC model with k states

Wireless Video Streaming, Fig. 2 Wireless video streaming flow

entire video content file; then the playout and download continues concurrently.

The wireless video streaming flow from the server side to the client side includes: encoder, network, decoder, and display, as shown in Fig. 2.

- *Coding and compression:* In order to transmit rich video content through a bandwidth limited network, the original video information needs to be compressed. Video compression formats define the way to represent the video and audio as a file or a stream. Video codec, a device or software, encodes or decodes a digital video based on the video compression format.
- *Network:* Common transmission network that is considered in the video streaming is wireless network. For the wireless network, it includes cellular network, wireless local area network (WLAN), vehicular network, and sensor network. Transmission network condition will greatly affect the video quality. There are three major factors that will influence video quality: TCP throughput, which represents the bandwidth; delay, which depends on the network capacity; and packet loss, which is due to unreliable transmission.
- *External factors:* Apart from the above factors, there are some external factors influencing wireless video streaming. The following are external factors: video service type, whether the video is live streaming video or Video-on-Demand; video length, It has been proven that users have different viewing

behaviors for videos of different lengths; and video popularity, generally, people prefer to watch popular videos.

Recently, a new class of video transport techniques has been introduced for transmission of video over varying channels such as wireless network. These transport techniques, called adaptive streaming, vary the bit rate and quality of the transmitted video to match the available channel bandwidth and alleviate the problems caused by network congestion, such as large latency and high packet loss rate. DASH, Dynamic Adaptive Streaming over HTTP, is a new international standard for adaptive streaming (Dynamic Adaptive Streaming Over HTTP 2010), which enables delivering media content from conventional HTTP web servers. DASH works by splitting the media content into a sequence of small segments, encoding each segment into several versions with different bit rates and qualities, and streaming the segments according to the requests from streaming client. On the client device side, the DASH client will keep monitoring the network and dynamically select the suitable version for the next segment that need to be downloaded, depending on the current network conditions.

Key Applications

Wireless video streaming is an efficient and fundamental video transmission pattern in streaming

media. There are many applications of wireless video streaming in the field of streaming media. In terms of real-time video streaming, most are related to wireless video streaming. For example, live video and video conferencing are all applications of wireless video streaming. Common transmission networks that are considered in the video streaming include IP network and wireless network. And for the wireless video streaming, the network it uses is a wireless network which includes cellular network, wireless local area network (WLAN), vehicular network, and sensor network.

Future Directions

For wireless video streaming, there are three aspects that need to be improved in the future:

- *Improve transmission channel quality.* Transmission network condition will greatly affect the video quality in the wireless video streaming. There are three major factors that will influence video quality: TCP throughput, delay, and packet loss. TCP throughput influences the bandwidth of transmission, the later cause frame loss in wireless video streaming. Thus, we should improve the quality of transmission channel in the future.
- *Reduce interference on the transmission channel.* The channel will change continuously due to various influencing factors during transmission. This phenomenon will greatly affect the quality of the video in the wireless video streaming. Thus, we must minimize the interference of the channel's time-varying video quality.
- *Improve video coding efficiency.* Improve video coding efficiency can increase the transmission quality of video to a certain extent. So we should improve it in the future.
